

## Reply to Editor's comments

### 1. Editor comment:

In the abstract you wrote "when combined with existing knowledge of radiative forcing."

Where I can find this in the paper? Please be explicit what do mean with radiative forcing.

### Authors' response:

We write about this in section 5.1, (lines 518-524 in the revision). To make things more explicit at an early stage we have included a sentence where we explain explicit which forcings that are relevant on page 1, lines 23-25.

### 2. Editor comment:

"In many recent papers the two-regime scaling hypothesis is presented as one that has been tested against data. "

Provide references (see sect. 6., p. 22. Last paragraph)

### Authors' response:

We have replaced "Many recent papers" with references to Lovejoy & Schertzer 2012, Lovejoy et al 2013.

### 3. Editor comment:

"It was argued by Lovejoy and Schertzer (2012b) that the Holocene part of the Greenland ice core GRIP  $\delta 180$  is exceptionally stable compared to other proxy-based reconstructions of North-Atlantic temperature, but we observe similar stability also for the stable isotope records from Greenland ice cores GISP2 and NGRIP, and the Antarctic ice cores EPICA, Vostok and Taylor dome.

I cannot find this in the paper. At least there shall be reference or are you referring to another section in the paper. I guess these statements are not suitable at this section of the paper. (See sect. 2, p. 5, last paragraph.

### Authors' response:

In this paragraph it is referred to some results of our scaling analyses, presented in the supplementary material sect. 2. It is therefore indeed unsuitable to include this in Sect. 2. The purpose of this paragraph is to justify our decision to analyze time series from deep ice cores from Greenland and Antarctica. Lovejoy states that GRIP Holocene paleotemperature is exceptional, and that the low value of beta/lack of scale break should therefore be ignored. We have rewritten and moved the entire paragraph in the revision, it is now found in Sect. 5.3.1, (lines 587-598).

We have added a reference to the results in supplementary Material in Section 6,

lines 646-648

#### 4. Editor comment:

Line 625: A number of theories and models exist for the mechanism of these events, see e.g., Dokken et al. (2013). This and other studies indicate that the DO-variability is internal and not a direct response to external forcing

Please be more explicit, what you mean. Avoid "this and other studies" without giving the corresponding reference.

The following discussion: there seem to be indications for patterns of common periodicities (Wirtz, " Mid-Holocene regional reorganization of climate variability: Analyses of proxy data in the frequency domain") at different scales.

#### Authors' response:

We have changed from "this and other studies" to "that study".

With regards to the Editor's reference to the Wirtz et al. paper, we shall here make some remarks on periodicities versus scaling behaviour. The more traditional climatology approach to climate variability is to identify oscillations associated with spatial patterns (EOFs). Sometimes these spatiotemporal patterns correspond to physical modes in the climate system, but often they do not. They are just the result of an empirical decomposition of the observed spatiotemporal signal that explains a considerable fraction of the total variance.

A scaling description is a much more crude and parsimonious approach. The observation of power laws in climate data does not in itself reveal anything definite about the underlying physics. This has been a long-standing debate in the complex-systems community, but so far nobody has come up with a universal explanation of power-laws in Nature. Identification of a large number of oscillatory modes is not inconsistent with a scaling description of temporal records. On the contrary, these descriptions may be complementary. In the spatiotemporal data for the instrumental period, modes have been identified on interannual, decadal and multidecadal scales and, for the same data, we find near-perfect scaling behavior both in local and global time records in this range of time scales.

There is no reason why the situation should be different on centennial to millennial time scales. However, on these time scales we in general have too short records within the Holocene to make meaningful estimates of a scaling exponent. Operating with a time resolution of 100 yr we only have 20 independent data points in 2 kyr multiproxy reconstructions and only 100 points in full Holocene reconstructions. In Fig. 5 and the corresponding text we show that the Moberg reconstruction may have somewhat higher power on millennial scale than is likely to be produced by a single scaling regime model, but that the scaling exponent for the low-frequency scaling regime estimated from a two-regime model is so uncertain that it even encompasses  $\beta_2=0$ . In Fig. 8 we show that the Moberg record is consistent with a two-regime description of the Moberg record, as well as with a description in terms of a single scaling regime superposed on a growing millennium period oscillation.

However, the statistical uncertainty of the latter is considerably smaller on the long time scales, and thus is a “better” statistical model. The literature offers various explanations of this oscillation, e.g., as a combination of, volcanic and solar forcing, but even without such explanation the oscillation is not less plausible than a second scaling regime with  $\beta_2 > 1$ .

Thus, and this is our main message, neither higher spectral slopes on scales longer than a century, or detection of strong oscillations on these scales give reasons to prefer a two-regime scaling model to the simpler one-regime model for parsimonious statistical model for surface temperature variability in the Holocene.

#### **5. Editor comment:**

Some statements seem to be over-confident, e.g. the glacial variability is not characterized on a global scale by the Greenland ice core records. Therefore some formulations are too strong, as e.g., "The dominating Quaternary climate state is the glacial, and temperature proxies from the last glacials take the form of a non-Gaussian intermittent stochastic process, displayed in its full glory by the Dansgaard-Oeschger events."

#### **Authors' response:**

After reflecting over this formulation and potential over-confident/inaccurate wording, we would like to remove this entire sentence from sect. 6 p. 20.

We also note that we use very similar wording two other places in the ms:

- 1) Sect. 1, p. 3: "Since glaciation is the dominating climate state in the Quaternary, the spectra obtained in those papers are typical for glacial climate."
- 2) Sect. 6, p. 19: "Since the glacial climate state is the dominating state in the Quaternary, the Holocene temperature variability is strongly suppressed when time series covering 100 kyr or longer are used to estimate scaling exponents."

We think a more precise formulation for the two sentences would be something like:

- 1) "Since the Quaternary climate is characterized by numerous long glacial periods and subsequent abrupt transitions into much shorter interglacials, the spectra obtained in these papers are essentially dominated by the information from the glacial climate state.
- 2) "Because the durations of the late Quaternary interglacials are generally much shorter than for the glacials, the Holocene temperature variability is strongly suppressed when time series covering 100 kyr or longer are used to estimate scaling exponents."

#### **6. Editor comment:**

Some formulations are too general (at least for me), e.g., " There are cycles, but the Earth rarely repeats itself. The Eemian was similar to the Holocene, but also very

different, the most striking difference being the evolution of human civilisations."

It is one prominent difference, but the sea level change was also a striking feature, etc.

**Authors' response:**

In the revision we have written: "...one striking difference being the evolution of human civilisations and the resulting anthropogenic climate forcing."

**7. Editor comment:**

some typos like " horisontal" or " Our conclusion is that he ..." please check!

**Authors' response:**

The mentioned typos have been corrected, and the revised manuscript will be proofread before submission.

**8. Editor comment:**

".. is the Quaternary in which the Earth's climate has been in a bistable state shifting between glacials and interglacials. The methodology and interpretations are based on this choice of the parameters ( $\tau_{max}$ ,  $t$ ). We don't see anything wrong with that, as long as one is mindful on that this is a choice, and recognises that there are other, equally valid, choices. If the issue is understanding of the present and future climate in our present interglacial state, we don't believe this choice is useful, simply because it ignores the knowledge that the Earth at present resides in an interglacial state and probably will continue to do so as long as there is human civilisation and anthropogenic forcing on this planet." It sounds philosophical. You can be more concrete/explicit and provide some references.

Furthermore, the whole analysis would be more convincing if you re-examine the analysis by Huybers. Related to this: line 750ff: be more precise about many recent papers. Is your finding in contrast to "In the the physics controlling centennial and longer-timescale temperature variability appears to be distinct from that of shorter timescales?" I guess some more physical arguments would help.

**Authors' response:**

The passage criticized for being "philosophical" is a response to Lovejoy's referee report, which is not less philosophical. It is an attempt to discuss that the concept of scaling is not possible to define uniquely in a non-stationary system that shifts between different states. The rest of the paper offers numerous concrete explicit examples and references. We have replaced "many recent papers" by proper references; see the response to Editors 2. comment.

The editor's comment "I guess some more physical arguments would help," and the request that we should re-examine the analysis of Huybers & Curry:

We write in our ms: "Huybers and Curry (2006) suggest that the power-law

continuum in the spectrum of surface temperature on time scales between one year and a century is a result of an inverse cascade in frequency space driven by the seasonal cycle forcing. The non-stationary scaling regime from century time scale and longer is proposed to be the result of a nonlinear response to the Milankovitch cycle forcing.”

The physical arguments offered by Lovejoy and Hyubers and Curry are nothing but a paradigm within which they try to understand the observation data. There is no physical modeling involved in those papers. We have alternative arguments to offer, and this is now discussed in a new paragraph in the introduction (lines 86-97 in the 3. revision). Here we give references to six of our recent papers which all deal with physical interpretation to some degree, and one paper by Geoffroy et al. (2013) dealing with two-box energy balance models fitted to CMIP5 simulations.

We will emphasize, however, that when we propose the single-regime model as a better and simpler option, it is a statistical model choice based on an assessment of the observation data, not on an assessment of a physics paradigm. This hypothesis-testing approach is the essence of Shaun Lovejoy’s criticism against our paper. In his review reports Lovejoy try to tell us that statistical hypothesis testing and scientific reasoning are two different things. The editor should respect that we disagree with him on that, and avoid forcing us to a loss of focus on the data analysis issues, which is the theme of the present paper.

#### **9. Editor comment:**

Some statements of the noise due to the recorder systems shall be adequate. There is a huge amount of literature about this, but you may select some of them related to your time series (ice cores and temperatures). You wrote: "Correcting for proxy noise is outside the scope of the present study, and we will therefore avoid studying composite spectra based on different reconstructions spanning different time scales and climatic states, and based on different proxies and reconstruction techniques."

I think you cannot completely ignore this, and I would like to see in the discussion at least an attempt to write cautious notes. You are claiming quite general statements about glacial-interglacial variability, so some discussion is necessary.

#### **Authors’ response:**

We have included a discussion of uncertainties in Sect. 2., (lines 149-166 in the revision), and explain why uncertainties cannot invalidate our main result.

#### **10. Editor comment:**

it is a little bit subjective, but I find the wording “macroweather” regime ( $\beta \approx 0.2$  for time scales from 10 days to 100 yr) not helpful. What is the physics behind this?

**Author' response:**

We share the editor's view that the "macroweather" concept is "not helpful", but it is a very central concept in Lovejoy's work on the different scaling regimes. We don't think it is reasonable to require that we shall explain physics we don't believe in.

**Editor:**

In a similar way: statements like "... made similar observations and concluded that GCM's do not predict climate, only macroweather." I cannot see the physics behind this.

**Authors' response:**

Again, this is Lovejoy's statement, not ours, and it is in the title of a recent paper of Lovejoy, Schertzer and Varon. Since the editor doesn't like it, we have removed it in the revision, since it isn't absolutely necessary to include it here.

**11. Editor comment:**

"However, by starting in the Little Ice Age the series are strongly influenced by steadily increasing solar, as well as anthropogenic, forcing." I am not sure if this is correct with respect to the solar forcing.

**Authors' response:**

From the abstract of Vieira et al., A&A, 531 (2011), "In this paper the TSI increases from 1364.5 W/m<sup>2</sup> during the Maunder minimum to 1366 W/m<sup>2</sup> today." This corresponds to  $1.5/4=0.4$  W/m<sup>2</sup> in radiative forcing, which is of course not much compared to the estimated anthropogenic forcing of about 1.6 W/m<sup>2</sup>.

We think it is reasonable to mention solar forcing, but perhaps downplaying its importance by changing the text to: "...strongly influenced by steadily increasing anthropogenic, and to a lesser extent, solar forcing.

## A synthesis of our disagreements with Shaun Lovejoy

From Shaun Lovejoy's scientific publication record and the discussion of this paper (Paper A) and an accompanying paper in ESDD (paper B<sup>1</sup>) it seems clear to us that the main disagreements are rooted in a conflict between Lovejoy's strong adherence to a particular paradigm within which he understands climate variability on a vast range of time scales, and our efforts to challenge that paradigm. Our understanding of Lovejoy's position is:

Temporal variability can be understood within the unifying statistical model framework of multiplicative cascades (multifractality). Within this framework the climate is naturally intermittent and will switch between different states of varying duration. For instance, the glacial/interglacial transitions and the shifts between stadials and interstadials associated with DO events during the last glaciation, are perceived as consequences of this multifractal scaling model. Since all the various climatic states are expressions of this multiplicative cascade, the information about the scaling structure is present in the time records at all times. For instance, the two scaling regimes that are clearly discerned in Greenland ice-core records during the glaciation are also present in the Holocene, although the scale break may be less discernible. Moreover, the multiplicative cascade framework is universal, and empirical multifractal analysis universally makes sense. It is only the *degree* of multifractal intermittency that may differ; therefore there is no need for hypothesis testing where the multifractal model is tested against other statistical models.

During the ESDD discussions Lovejoy characterize us as believers in "archaic" quasi-Gaussian statistical descriptions. This is far from true. We have no preconceived ideas about the validity of any particular description. But we believe that all paradigms deserve to be challenged, and in particular those that are not based on a description from first physical principles. Our project is to formulate plausible alternative models and use them as null hypotheses in statistical hypothesis testing.

The present paper is focused on Holocene climate and refuses to take as an axiom that the two regimes found in the glacial state are manifest in the Holocene temperature records. Instead, we treat this as a hypothesis that is tested against a single-regime null hypothesis, by using data from the Holocene only. Our results so far are that the single-regime hypothesis cannot be rejected. It does not, of course, prove that the two-regime hypothesis is false.

In his last referee comment to paper A, Lovejoy spends considerable effort on criticizing paper B, which deals with paleotemperature records from the last glacial period. Paper B demonstrates that the scaling within stadial and interstadial stages is very similar to the single-regime scaling we find for the Holocene. Moreover, a monofractal model for this variability is not rejected by the data. The entire glacial record (including the stadial/interstadial transitions) exhibits a scale break on millennium time scale in all structure functions.

Surprisingly, each regime exhibits monoscaling, and the scaling characteristics observed can easily be reproduced in synthetic data consisting of a fractional Gaussian noise superposed on a process with randomly distributed jumps. These characteristics cannot be reproduced in data generated by a multifractal cascade model.

Thus, from paper B, a picture emerges suggesting that the Holocene and stadials/interstadials can be considered as stages exhibiting similar, single-regime scaling, and the second scaling regime during glaciation is a direct consequence of the stadial/interstadial transitions. In this picture, Nature's "humming" is a monofractal noise interrupted by transitions which need to be explained by nonlinear dynamics, e.g., by bifurcations, and not as a consequence of a hypothesised multiplicative cascade. Evidence for the existence of such bifurcations associated with DO events has been presented in a recent paper by M. Rypdal (2016)<sup>2</sup>.

The trace moment analysis routinely employed by Lovejoy *assumes* multifractality and indiscriminately produces intermittency parameters for synthetically generated processes which are known not to be multifractal. The implication is that he finds multifractality everywhere, just in different degree. But locked to this paradigm, multifractality becomes an empty and uninteresting concept. What can multifractality explain if everything is multifractal?

The power of statistical modeling should be to serve as a guide to discern the underlying physics. Therefore an essential step in any scaling analysis should be to rule out other plausible statistical models. Papers A and B discussed here are attempts to introduce a more sound practice in scaling analysis of climatic time series and thereby reduce the risk of type I statistical errors (false positives).

The spatial dependence of the scaling properties is another fundamental disagreement. A recent paper by Fredriksen and Rypdal (2016)<sup>3</sup> investigates scaling properties in numerous instrumental, reanalysis and GCM data sets. They find that there are systematic differences in the spectral exponent  $\beta$  between land/ocean and local/global areas. For instance, on time scales between 1 and 10 yr, a value  $\beta > 1$  is typical for many marine sites, while continental land sites may have  $\beta \approx 0$ . These systematic patterns of difference most likely extends to longer time scales, and they have important implications when analyzing scaling properties in proxy-based reconstructions. Our position is that there is nothing exceptional about the scaling found in paleotemperature from Greenland ice core records, compared to the SST reconstruction referred to by Lovejoy (Berner et al. 2008.) Finding  $\beta > 1$  in one record, and  $\beta < 1$  in another record representing another dynamical regime, does not indicate that the records represent different scaling regimes. From our point of view this is simply a manifestation of the spatiotemporal climate variability on Earth.

## List of relevant changes in revision 3 of the manuscript

1. In Sect. 1, p1, l 23-25, a sentence is included where it is explained explicitly what we mean by radiative forcing.
2. A number of sentences are reformulated in response to the Editor's comments to ensure more careful and precise wording. See e.g. Sect. 1, p3, l66-68, Sect. 2, p4, l128, Sect. 6, p20, l664-667.
3. In Sect. 1., p3, l86-97, a new paragraph is included where it is described from our point of view, using physical arguments, how scaling can be used to describe the temperature variability in the climate system.
4. In Sect. 2, p5, l149-166, a new paragraph is included discussing uncertainties in the proxy-based reconstructions, and it is explained why uncertainties cannot invalidate our main result.
5. In the 2<sup>nd</sup> revision, Sect. 1, there was a paragraph about the fluctuation analysis, which is now moved to Subsect. 3.4. In addition, some effort has been made to avoid confusion regarding the exponents  $H$ ,  $h$  and  $\beta$  introduced and described in the 2<sup>nd</sup> revision in Sect. 1 and 3. In the 3<sup>rd</sup> revision  $h$  and  $H$  are mentioned respectively only once, when defining the scaling function in Subsect. 3.3.  $\beta$  is used all other places.
6. For the EPICA Dome C data set and all associated results, the abbreviation EDC is now used instead on "EPICA".
7. The last paragraph of Sect.2 in the 2<sup>nd</sup> revision has been rewritten and moved to Subsect. 5.3.1 in the 3<sup>rd</sup> revision. What is discussed here is the question of whether the paleotemperature records from Greenland ice core data are exceptional or not.
8. A paragraph has been included in Sect. 1, p4 l106-113 describing what type of analyses that will be conducted in our study and what type of data will be used.

# Are there multiple scaling regimes in Holocene temperature records?

Tine Nilsen<sup>1</sup>, Kristoffer Rypdal<sup>1</sup>, and Hege-Beate Fredriksen<sup>1</sup>

<sup>1</sup>Department of Mathematics and Statistics, University of Tromsø The Arctic University of Norway, Tromsø, Norway

*Correspondence to:* Tine Nilsen (tine.nilsen@uit.no)

**Abstract.** The concept of multiple scaling regimes in temperature time series is examined, with emphasis on the question whether or not a mono-scaling model with one single scaling regime can be rejected from observation data from the Holocene. A model for internal variability with only one regime is simpler, and allows more certain predictions on time scales of centuries when combined  
5 with existing knowledge of radiative forcing. Our analysis of spectra from stable isotope ratios from Greenland and Antarctica ice cores shows that a scale break around centennial time scales is evident for the last glacial period, but not for the Holocene. Spectra from a number of late Holocene multiproxy temperature reconstructions, and one from the entire Holocene, have also been analysed, without identifying a significant scale break. Our results indicate that a single-regime scaling climate  
10 noise, with some non-scaling fluctuations on millennial time scale superposed, cannot be rejected as a null model for the Holocene climate. The scale break observed from the glacial time ice core records is likely caused by the influence of Dansgaard-Oeschger events and teleconnections to the Southern hemisphere on centennial time scales. From our analysis we conclude that the two-regime model is not sufficiently justified for the Holocene to be used for temperature prediction on centennial  
15 time scales.

## 1 Introduction

The main focus of this paper is the scaling properties in paleotemperature records at centennial and millennial time scales. In particular we study the differences in variability between glacial and interglacial climates, and we discuss the justification of separating temperature variability on different  
20 time scales into distinct scaling regimes. The notion of “scaling” in climatic time series is based on the observation that the natural variability of the Earth’s surface temperature can be modelled as a persistent stochastic process, with superposed trends and quasi-periodic modes representing variability which is not included in the noise background. **The latter may be attributed to solar, volcanic, greenhouse gas and/or orbital radiative forcing, or internal climate modes such as the El Niño Southern Oscillation (ENSO).** There is a considerable body of literature suggesting that long-range memory (LRM) stochastic processes are good statistical models for de-seasonalised local and  
25

global temperature records on time scales from months up to a century or more (Koscielny-Bunde et al., 1996; Rybski et al., 2006; Efsthathiou et al., 2011; Rypdal et al., 2013; Østvand et al., 2014). The standard continuous-time stochastic LRM processes are the fractional Gaussian noise (fGn) and  
30 fractional Brownian motion (fBm). The latter is the cumulative integral of the former, and both are said to be scale-invariant (or scaling, or fractal), even though it is only the fBm process that exhibits statistical self-similarity (see Sect. 3.3). The strength of persistence, or memory, in an LRM stochastic process is described by the spectral exponent  $\beta$ ; the power spectral density (PSD) takes a power-law form  $S(f) \sim f^{-\beta}$ . The fGn has  $-1 < \beta < 1$  and stationary variance, while the fBm has  
35  $1 < \beta < 3$  and a non-stationary variance that grows in time like  $\sigma^2(t) \sim t^{\beta-1}$ . The fGn is persistent (exhibits long-range memory) if  $\beta > 0$ , and is anti-persistent if  $\beta < 0$ .

Because the terms “scaling regime” and “scale-break/deviation from scaling” might be ambiguous, we shall define how we use them in this paper. We shall follow the glossary of Kantelhardt (2011), where a scaling regime can be identified only if a power law is valid for scales spanning at least  
40 one order of magnitude, be it frequency or time scale. “Deviation from scaling” is synonymous with violation of Kantelhardt’s definition. The term “break in scaling” is used to separate scaling regimes with different  $\beta$ , where each regime complies with Kantelhardt’s definition and is valid for at least one order of magnitude.

Ditlevsen et al. (1996) analysed the scaling in high-resolution ice core data from Greenland. Two  
45 different overlapping time series were used to create a composite power spectrum, and from this a break in scaling was identified around centennial time scales. On time scales shorter than centennial the spectrum was flat ( $|\beta| \ll 1$ ), while on longer time scales a non-stationary regime with  $\beta \approx 1.6$  was found. One of the time series covers 0-91 kyr BP, and the other 0-3 kyr BP. This procedure of combining different time series into one power spectrum is problematic since the two time series  
50 reflect different climate states with different variability. The longer time series is dominated by the glacial state, while the short series only Holocene data. The different variability of the two states is seen clearly by direct inspection of the data, e.g., from comparing the Holocene part of the GRIP ice core (Fig. 10a) and the last glacial period from the same ice core (Fig. 12a). The standard deviation in the Holocene time series is less than half of the glacial one, and the latter looks more bursty. The  
55 records in Fig. 10a and Fig. 12a can be associated with different stochastic processes. The Holocene record is similar to an fGn with low persistence, while the records from the last glacial period exhibits strong intermittency and is associated with a high spectral exponent,  $\beta \approx 1.6$ .

Pelletier (1998) estimated the power spectra and scaling exponents from a Deuterium record from  
60 the Vostok ice core as well as from instrumental local data, and also created composite spectra from the records. Huybers and Curry (2006) and Lovejoy and Schertzer (2012b) have studied the scaling in multiple proxy data sets covering time scales from years to millions of years. Both report a break in scaling from fluctuations decreasing with scale ( $\beta < 1$ ) to fluctuations increasing with scale ( $\beta >$

0,  $\beta > 1$ ) on a transition time scale  $\tau_c \sim 10^2$  yr. The break in scaling is seen from composite spectra  
65 of paleotemperature records based on different proxies and reconstruction techniques, where many  
of the records span hundreds of kyr. Since the Quaternary climate is characterized by numerous long  
glacial periods and subsequent abrupt transitions into much shorter interglacials, the spectra obtained  
in these papers are mostly dominated by the information from the glacial climate state. Huybers and  
Curry (2006) suggest that the power-law continuum in the spectrum of surface temperature on time  
70 scales between one year and a century is a result of an inverse cascade in frequency space driven by  
the seasonal cycle forcing. The data-analysis evidence they present for this assertion is a bicoherence  
spectrum of the time series which shows strong phase correlation between the seasonal cycle ( $f_s =$   
1 yr) and pairs of frequencies ( $f_1, f_2$ ) satisfying the resonance condition  $f_0 = f_1 \pm f_2$ . This phase  
coherence is a result of a nonlinear interaction, but it does not imply that the low-frequency modes are  
75 driven nonlinearly by the seasonal oscillation. A low-frequency mode  $f_2$  with phase unrelated to the  
seasonal cycle will beat nonlinearly with the strong seasonal oscillation and produce weak sidebands  
on frequencies  $f_0 \mp f_2$ . This will produce a high bicoherence even if the nonlinear interaction has  
very little effect on the low-frequency mode. The non-stationary scaling regime from century time  
scale and longer is proposed to be the result of a nonlinear response to the Milankovitch cycle  
80 forcing. From the composite spectra, they infer scaling exponents in the range  $\beta = 0.37 - 0.56$  for  
time scales  $\tau < 10^2$  yr, and  $\beta = 1.29 - 1.64$  at longer time scales. Lovejoy and Schertzer (2012b)  
introduce three different scaling regimes: the “weather” regime ( $\beta \approx 2$  for time scales up to 10 days),  
the “macroweather” regime ( $\beta \approx 0.2$  for time scales from 10 days to  $10^2$  yr), and the “climate”  
regime ( $\beta \approx 1.4$  for time scales from  $10^2$  yr and longer). Common for these studies is that they don’t  
85 make a distinction between glacial and Holocene spectra.

An alternative set of physical arguments for scaling of global temperature on scales from months  
to millennia has been offered by Rypdal (2012); Rypdal and Rypdal (2014); Rypdal et al. (2015).  
Here, a linear power-law response to stochastic forcing yields the  $\beta < 1$  scaling, and the power-law  
response is interpreted from an energy balance perspective where energy is exchanged between dif-  
90 ferent parts of the climate system with different heat capacities and response times. A simple two-box  
model consisting of the mixed layer and the deep ocean is in fact sufficient to produce a signal that  
reproduces the scaling characteristics observed in CMIP5 models (Geoffroy et al., 2013; Fredrik-  
sen and Rypdal, 2016). Recently, Rypdal and Rypdal (2015) have demonstrated that the scaling in  
late Quaternary glacial climate can be described as abrupt transitions superposed on a  $1/f$ -noise  
95 background, and Rypdal (2016) found early-warning signals which suggest that the Greenland sta-  
dial/interstadial transitions during the last glacial period are results of bifurcations in a multidimen-  
sional dynamical system.

In the literature we find support our hypothesis of different scaling in glacial and interglacial  
climate, with the scale break at centennial time scales absent for the Holocene. Blender et al. (2006)  
100 analysed the scaling properties of a 10 kyr long climate simulation with a general circulation model

(GCM), where no scale break could be detected at centennial time scales. Roe and Steig (2004) found by using a short-range memory autoregressive (AR) model that the characteristic time scales for paleotemperature ice core records were significantly shorter during the Holocene than during the last glacial period. This study is important for our reasoning, but the idea needs to be adapted to a  
105 long-memory model.

We will analyse the scaling properties in regional and hemispheric multiproxy temperature reconstructions, and also proxy-based paleotemperature records reconstructed from deep ice cores sampled in Greenland and Antarctica. These ice core records are the most suitable data sets we could find for studying possible scale breaks both in the Holocene and the last glacial period, due  
110 to the high temporal resolution and long duration. We will separate the ice core records into glacial and interglacial time series and demonstrate the fundamentally different scaling properties of these climate states, and we will analyse other temperature reconstructions for the Holocene in search for a detectable scale break.

115 The paper is organized as follows: in Sect. 2 we address the issues of uncertainties and limitations of proxy-based reconstructions, and the implications for the existence of separate scaling regimes are discussed. Sect. 3 describes the scaling analysis methods employed, and information about the data used can be found in Sect. 4. The results from the analysis are presented in Sect. 5, and discussion and conclusion follow in Sect. 6.

## 120 2 The concept of multiple scaling regimes in the Holocene

Lovejoy and Schertzer (2012b) identify two scaling regimes in a number of Holocene temperature records. In instrumental data the transition time  $\tau_c$  is found to be 10-30 yr, in proxy/multiproxy reconstructions it is 40-100 yr, while for one of the ice core paleotemperature records it is approximately 2000 yr. Hence, it seems difficult to identify a universal  $\tau_c$  from the data examined in that pa-  
125 per. For the proxy/multiproxy reconstructions that were analysed in Lovejoy and Schertzer (2012b), the time period 1500-1979 was selected because it was common to all reconstructions, and the medieval warm period was avoided. However, by starting in the Little Ice Age the series are strongly influenced by steadily increasing anthropogenic, and to lesser extent, solar forcing. A pronounced linear trend has strong effect on the estimate of the scaling exponent from power spectra unless the  
130 time series is linearly detrended. The same is true for the Haar fluctuation analysis, which was also applied in Lovejoy and Schertzer (2012b).

Ditlevsen et al. (1996); Pelletier (1998); Huybers and Curry (2006); Lovejoy and Schertzer (2012b) all present composite spectra based on instrumental/reanalysis and/or proxy time series for scaling analysis. There are some problems related to this, in addition to the already mentioned aspect of com-  
135 bining time series from the Holocene/glacial climate state. The various data sets are representative

for different degrees of spatial averaging. This will affect the shape of the spectra and the estimates of the scaling exponent, because the high-frequency variability is reduced with increasing degree of spatial averaging. For the instrumental and **reanalysis** data we can obtain global averages, while proxy/multiproxy time series represent local, regional or at best hemispheric temperature. There is an important difference between composite spectra and spectra from multiproxy reconstructions. Multiproxy reconstruction methods generally take geographical weighting into account, and the aim is to obtain realistic high/low frequency variability throughout the time period covered by the reconstruction. Most composite spectra, on the other hand, do not handle these aspects in a satisfactory manner. An example of a well designed composite spectrum can be found in Laepple and Huybers (2014), where the proxy records have been corrected for noise, and the instrumental data used were extracted from the same location where the proxy records were sampled. No attempt was made to estimate a scaling exponent from this spectrum, but it is clear that no scale-break can be observed around centennial time scales.

The presence of uncertainties and noise in proxy based climate reconstructions is an unavoidable aspect when these types of data are used for statistical analyses. The different types of uncertainties can roughly be categorized into four groups: proxy, analytical, methodological, and dating uncertainties. A key problem is that the proxy-variable relationship is generally unknown or poorly understood, and also the evolution of this relationship through time. The proxy is considered a recorder of a climatic signal of interest, with time dependent sensitivity and possible discontinuities. The recorder system is also affected by non-climatic effects (noise), and distinguishing the signal and noise is a challenge. Many types of proxy archives demand sophisticated tools for constructing age models, hence the dating uncertainties.

In our analysis we make no attempt to account for these and other uncertainties. We can circumvent this notoriously difficult problem because uncertainties in the data cannot invalidate our main result, which is the identification of a type I statistical error in the existing literature. A type I error is the incorrect rejection of a true null hypothesis (a false positive). In our case the null hypothesis is a scaling model with a single scaling regime. Through Monte Carlo simulation of such a model we can establish a range of power spectral densities of the reconstructed temperature records that do not falsify the null hypothesis. We shall demonstrate that the null hypothesis cannot be rejected under the assumption that there are no uncertainties in the data. Hence, large error bars on these data will only increase the range of observations that are compatible with the single-regime hypothesis.

The techniques used to estimate the scaling exponent have inherently higher uncertainties on the longest time scales, due to sparse data on these time scales. A rule of thumb is that the scaling properties for a time series of length  $N$  should not be estimated on time scales longer than  $N/4$ , since the uncertainty on time scales longer (frequencies lower) than this is too large to make meaningful estimates. Suppose, for instance, we want to establish that we have scaling in annual data on scales up to 100 yr. Then we need a series which is at least 400 yr long. If we want to establish the existence

of a different scaling regime on time scales longer than 100 yr for a time series, we need to know with reasonable certainty the spectral estimates up to one millenium. As we will demonstrate in Sect. 5, this implies that we need annually resolved records with lengths spanning several millennia to bring the uncertainty of  $\beta$  below the limit needed to reject the single-regime scaling hypothesis.

Instrumental temperature data are not included in our analysis of multiple scaling regimes because previous studies do not show pronounced breaks in the scaling after detrending to account for influences from anthropogenic warming (Rypdal et al., 2013). The series are too short to detect scale breaks at centennial time scales. However, we use instrumental data in Sect. 3 for illustration of interesting features of various techniques for scaling characterisation.

### 3 Methods

In our data analysis we have used a number of tools. In general, the periodogram estimator for the power spectral density (PSD) is applied for the scaling analysis of paleotemperature time series in our study, and is the basis for significance testing when studying potential scale breaks in the time series. We have chosen the PSD because most readers are familiar with it, and because it is fully adequate for the purpose. Wavelet scalograms are not used to estimate scaling properties, but to visualize particular features in some of the time series. Structure functions are discussed to point out the general importance of higher-order statistics and to justify a monoscaling model (fractional Gaussian noise) for the internal temperature variability in the Holocene. The Haar fluctuation function is discussed because it is strongly advocated as the ultimate scaling analysis technique by e.g., Lovejoy and Schertzer (2012a). The detrended fluctuation analysis (DFA) is an estimation technique that is commonly used for scaling analysis of climatic records, but it will not be used in this paper because it turns out to be particularly insensitive to scale breaks on scales comparable, or larger than, one tenth of the record length. This feature will be discussed in some detail in section 3.5.

#### 3.1 Estimation of Power Spectral Density

The periodogram is applied as an estimator for power spectral density (PSD) for evenly sampled time series of length  $N$ . The stable istope records from Greenland and Antarctic ice cores have been linearly interpolated to obtain even sampling in time. All other records are provided with even sampling. The periodogram is defined here in terms of the discrete Fourier transform  $H_m$  as  $S(f_m) = (2/N)|H_m|^2$ ,  $m = 1, 2, \dots, N/2$ . The sampling time is the time unit, and the frequency is measured in cycles per time unit:  $f_m = m/N$ .  $\Delta f = 1/N$  is the frequency resolution and the smallest frequency which can be represented in the spectrum, while  $f_{N/2} = 1/2$  is the Nyquist frequency (the highest frequency that can be resolved). The periodogram has a poor signal to noise ratio, but since we are interested in studying the overall shape (scaling) of the spectrum, and not the power at specific spectral peaks, this is not a problem here. By presenting the periodogram

in a log-log plot, the scaling exponent  $\beta$  can be estimated by a linear fit to the power spectrum;  $\log S(f) = -\beta \log f + c$ . In the present study the periodogram is log-binned before fitting to ensure that all time scales are weighted equally (Østvand et al., 2014).

210 We have also considered other spectral estimators for the unevenly sampled stable isotope data from ice cores, such as the Lomb-Scargle periodogram (LSP), (Lomb, 1976; Scargle, 1982), or correlation slotting, Rehfeld et al. (2011). The main motivation for looking into different spectral methods is to compare biases in the spectra that could be wrongfully interpreted as breaks in the scaling. The papers by Rehfeld et al. (2011) and Broersen et al. (2000) demonstrate that irregularly  
 215 sampled data cause various problems for all spectral techniques. Slotting can be problematic because the covariance estimators may not be positive semi-definite, and could hence give negative values in the spectrum. Interpolation leads to underestimation of the spectral power at high frequencies, while the Lomb-Scargle periodogram suffers from the opposite bias: overestimation of the spectral power at high frequencies. The skill of the LS periodogram is, as demonstrated by Rehfeld et al. (2011),  
 220 dependent on the skewness of the distribution of sampling intervals. The bias will therefore differ from dataset to dataset. We have tested the performance of the method on surrogate data mimicking the ice core proxy data under study. The detailed results for this test are shown in supplementary material. In general the method performs well, but not much better than interpolation plus standard periodogram. Results presented in the main paper are obtained using only interpolation and the  
 225 standard periodogram. Scaling analysis of the ice core data based on the LSP is included in the supplementary material section 1.

### 3.2 Wavelet scalogram

The continuous wavelet transform is the convolution between a time series  $x(t)$  and the rescaled mother wavelet  $\Psi(t)$ ;

$$230 \quad W(t, \tau; x(t), \Psi(t)) = \int_{-\infty}^{\infty} x(t') \frac{1}{\sqrt{\tau}} \Psi^* \left( \frac{t' - t}{\tau} \right) dt', \quad (1)$$

where the asterisk indicates complex conjugate. The wavelet scalogram (WS) is defined as  $|W(t, \tau)|^2$ , and is plotted versus time and time-scale. The WS is used here as a supplementary tool to the Fourier spectra. Time segments before and after the time interval where we have data were padded with zeros, as described in Torrence and Compo (1998). The region in  $(t, \tau)$ -space affected by edge effects  
 235 is the region above the white line in the upper part of the WS-plot shown in, e.g., Fig. 11. Due to the uneven sampling of the data in this study, linear interpolation has been performed prior to computing the WS. At each time  $t$  there is a characteristic sampling period in the original time series, and hence a Nyquist period. This Nyquist period is marked as the lower white curve in the WS plots. The WS below that curve does not reflect observed variability.

240 We have chosen two wavelet functions as the basis for our study: the Morlet wavelet which is complex valued, and the Mexican hat wavelet (second derivative of a Gaussian) which is real valued. The

wavelet scalograms from these two wavelet functions provide different information. The Mexican Hat wavelet function resolves the timing of spectral peaks precisely, while the scale resolution is poor. For the Morlet wavelet function the opposite is true.

### 245 3.3 Structure functions and scaling function

A plethora of estimators have been developed for computing characteristic exponents for monoscaling long-range memory (LRM) processes. They all have strengths and weaknesses, but have in common that they give nonsense if the signal is not a mono- or multi-scaling process. Common for many papers by “LRM-skeptics” is the uncritical use of cookbook recipes for such estimators to data that are not scaling, for instance climatic time series dominated by a specific trend (e.g., Mann (2011)). Hence, more important than estimating a characteristic exponent is to examine the general scaling characteristics of the data. A classical and useful method is to examine the probability density functions (PDFs) of the time series as it varies on different time scales. Rather than computing and plotting the PDFs, it is more common to compute the statistical moments of order  $q$  of the distribution, and then plot these moments as a function of time scale  $\Delta t$ . **Estimators employing only second-order statistics, like the periodogram or the Haar fluctuation employed by Lovejoy and Schertzer (2012b) are not able to distinguish between scale-invariant fluctuations and variability due to trends or oscillations. Careful application of higher-order statistics like higher-order SFs has this ability. This can give us the possibility to separate distinct non-scaling dynamical features from the scaling, persistent noise background. In section 5.1 we shall demonstrate this usefulness on a multiproxy temperature reconstruction spanning two millennia.**

Given a stochastic process  $x(t)$ , the moments

$$S_q(\Delta t) \equiv E[|x(t + \Delta t) - x(t)|^q], \quad (2)$$

are called the structure functions (SFs) of the process. If the process is sampled at discrete times  $t = 1, \dots, N$  the empirical moments  $\hat{S}_q(\Delta t) = (N - \Delta t)^{-1} \sum_{i=1}^{N-\Delta t} |x(i + \Delta t) - x(i)|^q$  constitute estimates of the structure functions. For large  $\Delta t$  (when  $\Delta t$  is no longer a small fraction of  $N$ ) the number of independent terms becomes small, and the statistical uncertainty of the estimate becomes large. As mentioned in Sect. 2, a useful rule is that this limits the scales we can investigate to  $\Delta t < N/4$ .

270 Let us assume that  $x(t)$  is a self-similar, Gaussian, non-stationary stochastic process, i.e., a fractional Brownian motion (fBm). Then the structure functions defined on  $x(t)$  take the form,

$$S_q(\Delta t) \equiv E[|x(t + \Delta t) - x(t)|^q] = \Delta t^{\zeta(q)}, \quad (3)$$

where  $\zeta(q) = hq$  is the *scaling function* of the self-similar (monofractal) process and  $h = (\beta - 1)/2$  is the *self-similarity exponent*. By taking the logarithm of Eq. (3) we find the linear relationship between  $\log S_q(\Delta t)$  and  $\log \Delta t$ , where  $\zeta(q)$  is the constant of proportionality, hence the SFs appear

as straight lines in log-log plots with slope  $\zeta(q)$ . If the SFs have the form Eq. (3) (i.e., if the SFs are straight lines in log-log plot) so that  $\zeta(q)$  is defined, but  $\zeta(q)$  is not a linear function, then the process is multifractal. **It follows that monofractals belong to a subclass of the class of multifractals.** If the SFs are not straight, the process is neither multi- nor monofractal, but it may still have a bursty or  
 280 *intermittent* appearance **if the PDF of the fluctuations on the short time scales is non-Gaussian with flat tails.**

If a **monofractal** process is stationary, it is a fractional Gaussian noise (fGn), and the SFs are constant (flat) and contain no other information than the stationarity. However, as we shall see below, the SFs may still contain some useful information about the deviation from scaling if there are trends  
 285 or oscillations in the data. In order to expose the scaling properties (if any) of the process, the trick is to form the cumulative sum  $y(i) = \sum_{j=1}^i x(j)$  and then compute the SFs from this sum. The resulting SFs take the form

$$S_q(\Delta t) \equiv E[|y(t + \Delta t) - y(t)|^q] = \Delta t^{\zeta(q)} \quad (4)$$

where  $\zeta(q) = Hq$  is the scaling function.  $H$  is the **self-similarity exponent of the cumulative sum**  
 290  **$y(t)$  and the Hurst exponent of the stationary process  $x(t)$ .  $H$  is related to the spectral exponent  $\beta$  of  $x(t)$  through  $H = (\beta + 1)/2$ .**

The usefulness of the structure-function approach is illustrated in Figure 1. Panel (a) shows the eight structure functions corresponding to  $q = 1, 2, \dots, 8$  for the monthly global mean surface temperature (GMST) for the period 1880 – 2010 derived from the HadCRUT3 data set (Brohan et al.,  
 295 2006). The SFs are far from straight in the log-log plot, as they would be if the time series were non-stationary fractal (fBm) or multifractal. But the SFs are not flat either, as they would be if the time series were an fGn. The explanation for the upward bending of the curves is obviously the strong anthropogenic temperature trend.

The underlying scaling of the noise is exposed by computing the SFs for the cumulative sum,  
 300 as shown in Figure 1b. However, the corresponding scaling function, shown by the upper line in Fig. 1d, has the slope  $H \approx 1$ , which is always the case for a signal dominated by a strong trend. The true scaling of the noise appears after a second-order polynomial fit to the record has been subtracted. The SFs for the cumulative sum of the detrended record is shown in Fig. 1c, and the corresponding scaling function by the lower line in Fig. 1d. This line has Hurst exponent  $H \approx 0.85$ . The straight  
 305 appearance of the scaling function tells us that the GMST is monofractal, and simple tests on the PDFs at different scales show that it is Gaussian (Rypdal and Rypdal, 2010).

The scaling functions in Fig. 1d have been computed from the slopes of the SFs in the regime of scales  $\Delta t < 10$  yr where the SF-curves are straight. The bending of these curves for large scales are due to oscillatory modes on periods around 20 yr and 70 yr.

### 310 3.4 The Haar fluctuation function

A simple measure of scaling is the fluctuation analysis (FA) (for a brief review see Rypdal et al. (2013)). It defines the fluctuation function  $F(\Delta t)$  as the standard deviation of the data record after it has been filtered by a simple moving average with window width  $\Delta t$ , and hence measures the fluctuation magnitude as a function of scale  $\Delta t$ . The fluctuations are scaling if  $F(\Delta t) \sim \Delta t^{(\beta-1)/2}$ .

315 An issue with FA is which mean value to relate the fluctuation deviation to; the local mean in the window, or the mean of the entire data record. The latter is problematic if the fluctuations are monotonically growing with increasing scale. This problem can be circumvented by convolving the data record with the simple antisymmetric Haar-wavelet (Lovejoy and Schertzer, 2012a) rather than performing the moving average. For fluctuations growing with scale it measures fluctuation differences  
320 versus scale, whereas for fluctuations decreasing with scale it measures fluctuation relative to the local mean.

The simple definition given in Lovejoy et al. (2013) starts by defining the fluctuation on scale  $\Delta t$  as,

$$\Delta x_t(\Delta t) = \left| \frac{2}{\Delta t} \sum_{i=t}^{t+\Delta t/2} x_i - \frac{2}{\Delta t} \sum_{i=t+\Delta t/2}^{t+\Delta t} x_i \right|, \quad (5)$$

325 and then the Haar structure function is given by

$$S_q^{\text{Haar}}(\Delta t) = \frac{1}{N - \Delta t} \sum_{t=1}^{N-\Delta t} \Delta x_t(\Delta t)^q. \quad (6)$$

The Haar fluctuation function used extensively by Lovejoy and Schertzer in arguing for the existence of transitions between scaling regimes is defined as

$$F^{\text{Haar}}(\Delta t) = \sqrt{S_2^{\text{Haar}}(\Delta t)}. \quad (7)$$

330 In Fig. 2 we illustrate some features of the Haar fluctuation applied to the instrumental GMST. Fig. 2a shows the GMST and a trend computed by fitting a second order polynomial. The black thick curve in Fig. 2b is the Haar fluctuation function computed from the record in a log-log plot (the upper curve is shifted by a factor 10).

There are (at least) two different ways to model this record as a simple stochastic process. One  
335 is to assume that it is a linear combination of an fGn ( $\beta < 1$ ) and an fBm ( $\beta > 1$ ). The former will dominate the fluctuation function on the small scales, and the latter on the long scales. Hence this is a model that exhibits a scale break and two scaling regimes. We have estimated the slopes of the fluctuation function in these two regimes, and found  $\beta \approx 0.8$  on the short scales, and  $\beta \approx 1.6$  on the long scales. We then computed the weights of each process using the estimated variance of the  
340 GMST on the shortest and longest scales, respectively, and computed an ensemble of realizations of their linear combination. The red curves in Figure 2b constitute 20 realizations in such an ensemble (multiplied by a factor 10). These curves demonstrate that the observed Haar-fluctuation is consistent with this model, but also that the uncertainty in the model prediction on scales longer than a decade

is so large that that the observed fluctuation function here could also be consistent with a model  
345 where  $\beta < 1$ . Another obvious way to model the record is as a linear combination of the fGn and the  
quadratic trend. The resulting ensemble is shown as the blue curves in Figure 2b. The observed record  
is consistent with this model too, but the big difference is that in this case the model prediction on  
large scales is much more certain, and hence constitutes a “better” statistical model. An extra bonus  
is that the quadratic trend is physically well understood, since it corresponds closely to present  
350 knowledge about greenhouse forcing.

Thus, we have the choice between explaining the observation with a poor statistical model (many  
parameters, large prediction uncertainty, and no physics explaining the scale break) and a much  
better model (fewer parameters, lower uncertainty, and a clear physical explanation).

A common estimator for scaling exponents is the wavelet variance, i.e., to plot the variance of the  
355 wavelet coefficients versus scale in a log-log plot, and it is common to normalize the wavelet such  
that the slope for an fGn will be the spectral exponent  $\beta$ . In practice this can be obtained by squaring  
the Haar fluctuation  $S_2^{1/2}(\Delta t)$  and multiplying by the scale  $\Delta t$ , i.e., we compute  $\Delta t S_2(\Delta t)$ . In  
Figure 3 we generate an ensemble of 10 fGns of 1000 data points with  $\beta = 0.8$  and plot  $S_2^{1/2}(\Delta t)$   
for all realizations in the ensemble in Figure 3a, and  $\Delta t S_2(\Delta t)$  for the same ensemble in Figure  
360 3c. If we use the entire ensemble to estimate the slope we will get a quite accurate result (getting  
better the larger the ensemble), but if we estimate the slope from one realisation we make greater  
errors if we include the longer time scales in the fit. This is why some authors recommend not to  
include longer scales than  $1/4$  of the record length and others recommend no more than  $1/10$ . If we  
fit a straight line we have no reason to believe that the Haar fluctuation gives less accurate estimates  
365 than the Haar wavelet variance. However, by inspecting the two for one particular realization in the  
ensemble, as is done in Fig. 3b and d, we observe that the Haar fluctuation can present a break in the  
curve that visually is much more pronounced than in the corresponding Haar wavelet variance. This  
is nothing but a visual illusion (the two plots contain the same information); a curve that changes its  
slope from negative to positive is more easily perceived to represent different qualities than the curve  
370 that only changes its positive slope somewhat. Since all the curves are produced from realizations  
of the fGn, all scale breaks are spurious, and caused by the diverging statistical uncertainty in the  
high-scale end. Thus, if the underlying scaling is close to  $1/f$  noise, then weak trends or oscillations  
tend to appear as breaks in the Haar fluctuation curve, but are much less visible in the wavelet  
variance curve. A sound approach to graphical tools like this should avoid visualizations like the  
375 Haar fluctuation, which exaggerates such spurious breaks.

### 3.5 The detrended fluctuation analysis (DFA)

This estimator was invented by Peng et al. (1994) and first applied to climatic time series by Koscielny-  
Bunde et al. (1996). The technique performs an  $n$ -th order polynomial detrending of the cumulative  
sum of the data record on each time scale  $\tau$ , and computes the variance (fluctuation function)  $F_n(\tau)$

380 of the resulting residual as a function of  $\tau$ . A good introduction to the technique is Kantelhardt et al. (2001).

DFA performs very well when it comes to estimation of the scaling exponent of perfectly scaling signals. Errors arising from the finite length of the data record are smaller than for other estimators. However, since the nature of DFA is to perform detrending on all scales, the variance on a scale  
385  $\tau$  is strongly underestimated compared to the actual variance, even when the signal is perfectly scaling with no imposed trend. The method works for estimation of the scaling exponent because (in a perfectly scaling signal) this underestimation is the same on all scales. This underestimation of the true variance increases with degree of detrending (the order  $n$  of the polynomial), so even if the slopes of the curves  $\log F_n(\tau)$  vs.  $\log \tau$  remain the same as  $n$  increases, the variance goes down,  
390 as shown for instance in Fig. 4 of Kantelhardt et al. (2001). In effect  $F_n(\tau)$  does not measure the variance on scale  $\tau$ , but is rather a weighted sum of variances on shorter scales than  $\tau$ .

For this reason DFA shifts a scale break to longer scales, as is shown by Fig. 4(c) in the paper by Kantelhardt et al. (2001). We illustrate this in Fig. 4, where we have employed DFA to an ensemble of realizations of length 2000 time steps of a process which is a superposition of an fGn with  $\beta = 0.2$   
395 and an fBm with  $\beta = 1.8$ . The power spectrum exhibits a clear transition in the scaling with the center of the break located at the frequency  $f \approx \times 10^{-2}$ , corresponding to scale  $\tau \approx 1/f = 100$ . This break is shifted towards a larger scale ( $\tau \approx 250$ ) in DFA( $n = 2$ ), which is the DFA-order employed in Rybski et al. (2006). This means that a scale break at  $\tau \approx 100$  yr would appear in DFA of a 2000 yr record as a break at  $\tau \approx 250$  yr. But in Rybski et al. (2006) this is roughly the maximum time scale  
400 investigated by DFA for the various multi-proxy records, hence such a break could not have been detected by the methods employed in that paper. This demonstrates that DFA does not have the sensitivity on long time scales to detect scale breaks unless the break takes place at a transition scale which is at least an order of magnitude shorter than the length of the observed data record. For this reason DFA is not employed as an estimator in the present paper.

#### 405 **4 Data**

The scaling is analysed in seven proxy/multiproxy temperature reconstructions representing late Holocene temperature, one temperature reconstruction representing the entire Holocene time period, in addition to six reconstructions of stable isotope ratios from the deep ice cores GRIP, GISP2 and NGRIP from Greenland, and EPICA, Taylor dome and Vostok from Antarctica. Information and  
410 analysis results from GISP2, NGRIP, Taylor and Vostok is provided in supplementary material. From the available ice core time series we extract sub-series covering only the Holocene and only the last glacial period, respectively. For the GRIP ice core we also extract a time series covering 0 – 85 kyr BP. Since the exact timing of the transition between the Holocene and the last glacial period is slightly different for Greenland and Antarctica, we have chosen the start and end of the time series

415 carefully for each series, such that the transition is not contained in any of the “Holocene only” or  
the “glacial only” time series.

#### 4.1 Proxy/multiproxy late Holocene temperature reconstructions

We have chosen seven proxy- or multiproxy based temperature reconstructions for our study, and  
in order to avoid the trend effect from anthropogenic warming we have discarded data after 1850  
420 AD (see Table 1). All time series are given with annual resolution. A few of the reconstructions are  
based partly on the same raw proxy records, but we include all since the reconstruction methods are  
different. The Jones et al. (1998) multiproxy reconstruction represents northern hemisphere temper-  
ature. The Briffa et al. (2001) reconstruction represents the continental region 20° N – 90° N and is  
constructed from tree rings. The Esper et al. (2002) reconstruction is also based on tree rings and rep-  
425 resent the continental region 30° N – 80° N. The Huang (2004) reconstruction is based on borehole  
temperatures, integrated with instrumental temperatures and the multiproxy reconstruction by Mann  
et al. (1999). The Moberg et al. (2005) multiproxy reconstruction represent northern hemisphere  
temperature, and is smoothed on the shortest time scales, so estimates of the scaling exponents are  
restricted to time scales from 4 years and longer. The Mann et al. (2009) multiproxy reconstruction  
430 represents global temperature, and is smoothed up to decadal time scales. The Neukom et al. (2014)  
multiproxy reconstruction represents southern hemisphere temperature.

#### 4.2 Multiproxy full Holocene temperature reconstruction

The temperature reconstruction described in Marcott et al. (2013) covers the entire Holocene time  
period. The reconstruction is based on 73 proxy records with temporal resolution varying from 20 to  
435 500 years. The spatial distribution of proxy data is near global, and there is a high percentage of data  
sets from marine sites. The proxy records had been interpolated to 20-year resolution before con-  
structing the temperature reconstruction, and the final record is presented with a 20-year resolution.  
The reconstructed temperature gets gradually smoother as one goes back in time. This is observed  
from the time series itself in Figure 9a. From the supplementary material of the Marcott et al. (2013)  
440 paper it is clear that the proxy records covering the most recent time also in general exhibit the best  
temporal resolution. The reconstructed temperature data for the past 1500 years therefore represent  
high-frequency variability in a more realistic way than the remaining part of the reconstruction.

#### 4.3 The GRIP ice core

The European multinational research project “Greenland Ice Core Project” (GRIP) completed drilling  
445 a 3028 m deep ice core from central Greenland in 1992 (Dansgaard et al., 1993). Two GRIP data  
sets are used in this study, one with high temporal resolution covering 0 – 91 kyr BP (Ditlevsen  
et al., 1996), and one with lower temporal resolution covering 0 – 250 kyr BP (Greenland Ice-Core  
Project (GRIP) Members, 1993; Johnsen et al., 1997). The high-resolution data set was provided by

Peter Ditlevsen at the Centre for Ice and Climate, Niels Bohr Institute, University of Copenhagen,  
450 personal communication. Both data sets are used to estimate the spectral exponents, but the results  
shown in Sect. 5 are for the high resolution time series. Both temperature reconstructions are based  
on  $\delta^{18}\text{O}$ .

#### 4.4 The EPICA Dome C ice core

The European Project for Ice Coring in Antarctica (EPICA) drilled two deep ice cores in Antarc-  
455 tica between 1996 and 2006. Here we focus on the core from dome C at the East Antarctic Plateau  
(abbreviated EDC onwards), covering the past 740 000 years (EPICA community members, 2004;  
Jouzel et al., 2007). The temperature reconstruction is based on  $\delta D$ .

## 5 Results

### 460 5.1 Results for late Holocene multiproxy reconstructions

Three approaches are used to detect a scale break from the spectra of the seven multiproxy temper-  
ature reconstructions. The first is to assume a scale break at exactly 100 years, and then estimate  $\beta$   
for long and short time scales, and determine the uncertainties for each estimate. By this approach  
we demonstrate that scale breaks may occur by chance from a mono-scaling model, without being  
465 statistically significant. The second approach is to use a procedure for automatic detection of a scale  
break from a two-scaling regimes hypothesis, and show that a wide range of time scales  $\tau_c$  for the  
break, and a wide range of scaling exponents  $\beta_1, \beta_2$ , arise by applying the procedure to a Monte  
Carlo ensemble of monoscaling time series. We also employ the structure function approach, and  
show that the enhanced power at large scales is associated with an oscillation with characteristic  
470 scale around 500 yr.

Fig. 5 illustrates the procedure and results for the Moberg temperature reconstruction, using the  
first approach. The spectral exponent  $\beta$  is estimated from the standard periodogram of the recon-  
structed data, for time scales shorter than  $10^2$  yr ( $\beta_{1,\text{data}}$ ) and for time scales longer than  $10^2$  yr  
( $\beta_{2,\text{data}}$ ), as shown in Fig. 5b. A Monte Carlo (MC) ensemble of synthetic fGn's with 2000 mem-  
475 bers is then constructed with  $\beta_{1,\text{data}}$ , and from the spectra (Fig. 5c), the same estimation technique is  
used to estimate  $\beta_{1,\text{MC}}$  and  $\beta_{2,\text{MC}}$  for each realization. From the distribution of the estimated  $\beta_{1,\text{MC}}$   
and  $\beta_{2,\text{MC}}$ , the 95% confidence ranges are computed. Fig. 5d shows the mean and 95% confidence  
range for  $\beta_{2,\text{MC}}$ . Since the blue line ( $\beta_{2,\text{data}}$ ) is within the confidence range for a MC ensemble  
of fGn's with  $\beta=0.8$ , the single-scaling regime hypothesis cannot be rejected. Results for all seven  
480 reconstructions are shown in Table 1.

For the Esper et al. (2002) reconstruction the estimate of  $\beta_{1,\text{data}}$  is slightly outside the confidence range, but this is due a bias of the synthetic fBm for  $\beta$  slightly higher than unity (see supplementary material section 1.1 for further details). This deviation should therefore be ignored.

From the second approach we obtain for each reconstruction two values of  $\beta$  and a time for the scale break. The procedure is to fit two line segments with slopes  $\beta_1$  and  $\beta_2$  to the log-log spectrum, such that they join at  $f = f_c = 1/\tau_c$ . The two slopes and the transition frequency  $f_c$  are the parameters to be fitted by an ordinary least-square procedure. Results for the seven temperature reconstructions are provided in Table 2, where also the differences in  $\beta$ -values are included. The scale-break hypothesis of Lovejoy and Schertzer (2012b) states that the the difference  $\beta_2 - \beta_1$  should be around unity. This procedure has also been tested on a Monte Carlo ensemble of mono-scaling fGn's. Fig. 6 shows a histogram of the differences in estimated  $\beta_2$  and  $\beta_1$ . The histogram shows that the scale breaks detected by this procedure in the multiproxy records are not unlikely to be detected in records with a single scaling regime, i.e., their detection does not reject the single-scaling regime hypothesis. A histogram of  $\tau_c$  also shows a broad distribution, (figure not shown).

In Figure 7a we plot SFs for the cumulative sum of the Moberg multiproxy reconstruction. The SFs are straight in the log-log plot up to around 500 yr, but then there is a broad bump. By examining the record it becomes apparent that this bump is associated with an oscillation with period of order of a millennium that involves the Medieval Warm Anomaly (MWA) high and the Little Ice Age (LIA) low. The fact that this oscillation shows up in the high-order SFs indicates that its amplitude is larger than consistent with the underlying persistent noise. If we fit the SFs by straight lines up to 500 yr we obtain the scaling function in Figure 7b with slope  $H \approx 0.87$ , in very good agreement with what was found from the instrumental data. If this oscillation were a manifestation of a new scaling regime with  $\beta > 1.4$  ( $h > 0.2$ ,  $H > 1.2$ ), we should expect the SFs in Figure 7a to be straight with slope  $q$  on scales  $> \tau_c$ , and the scaling function obtained by fitting lines to the SFs on these scales to have slope  $H = 1$  (this is easily demonstrated by Monte Carlo simulations). What we observe, however, is a downward bend caused by the oscillation discussed above. It can be correctly argued that this bend is not statistically significant, since we only have one sample of it, but it demonstrates very clearly that there are cases where fluctuation measures like the periodogram or the Haar fluctuation function will suggest a new scaling regime with higher scaling exponents (see Figure 8b), while the SF method will suggest oscillations.

The issue of modelling the fluctuations on multi-century time scale as a second scaling regime or an oscillation is illustrated in Fig. 8. The idea is the same as in Fig. 2, but now the “trend” is modelled as a growing oscillation on the form  $A t \sin[\omega(t - \varphi)]$ . The Moberg record and the fitted trend is shown in Fig. 8a, and Fig. 8b shows the Haar fluctuation of the record along with realisations of a model comprised of a linear combination of an fGn and an fBm (red curves), and realizations of a model comprised of a linear combination of an fGn and the oscillatory trend. Again, the observation is consistent with both models, but the latter exhibits smaller uncertainties at longer scales, and

hence is a better statistical model. The attribution study of Rypdal (2015) points at a combination of volcanic and solar forcing, with greater weight to volcanoes, as the main driver of this oscillation.

520 Rypdal and Rypdal (2014) show that the residual after subtracting the response to this forcing is well modelled as an fGn with  $h$  compatible with what was used for the short scales in Figure 8b. Thus, compared to a two-scaling regime model, the simpler and more accurate statistical model of the Moberg record is to model the internal variability as a persistent fGn for all scales up to the length of the record, superposed on a forced oscillatory trend.

525 An important feature shown by the scaling functions in Figs. 1 and 7 is that the background noise in GMST is monofractal. It is also Gaussian. This means that a fractional Gaussian noise is a good model for these fluctuations, and hence that all essential information is contained in the scaling exponent and the variance. This is also true for ice core data in the Holocene, while during the last glaciation, ice core data are neither monofractal nor multifractal. In an accompanying paper from our  
530 research group (Rypdal and Rypdal, 2015) it is demonstrated that if the transitions between stadial and interstadials associated with DO events and glacial/interglacial transitions are removed from the ice-core records, the remaining fluctuations scales roughly as a  $1/f$  noise ( $\beta \approx 1$ ) on time scale longer than a century. In other words, over the length of the Antarctic ice core record (800 kyr) the temperature variability can be described as a series of glacial/interglacial transitions, and within the  
535 glacial periods; a series of stadial/interstadial transitions, superposed on a background  $1/f$  noise. This suggests that Holocene variability should also exhibit this scaling of the climate noise, and the analysis of the Moberg record we have made here does not reject that hypothesis.

## 5.2 Results for the full Holocene multiproxy reconstruction

The reconstruction by Marcott et al. (2013) has been analysed with the periodogram in a particular  
540 way to take into account the increasing smoothness of the record as one goes backward in time. **The wavelet scalogram in Fig. 9b illustrates that the wavelet power on long time scales is substantially higher in the early Holocene as compared to the later half.** If we compute the standard periodogram for the full time series, the resulting spectral exponent is  $\beta = 2.9$ . The power is artificially low at high frequencies, and this is corrected by dividing the time series into segments  $S_n$  of lengths  
545  $2^n \times 400$  yr, with  $n = 0, 1, 2, \dots, 5$ , and starting with the most recent period. Hence,  $S_1 = 50 - 450$  yr BP,  $S_2 = 50 - 850$  yr BP,  $S_3 = 50 - 1650$  yr BP,  $S_4 = 50 - 3250$  yr BP,  $S_5 = 50 - 6450$  yr BP, and  $S_6 = 50 - 11290$  yr BP (longest possible record, shorter than  $2^5 \times 400$ ). The periodogram was estimated for each segment, and then a new power spectrum was created using only parts of each segment assumed to be trustworthy with regard to preserved variability. All of  $S_1$  was included, while  
550 for  $S_2, \dots, S_6$  only the low-frequency parts were included (none overlapping). By this composition, the resulting power spectrum represents the variability on all time scales more correctly. Fig. 9c shows the spectra of all six segments, in addition to the corrected spectrum (blue dots, black line). The value of  $\beta=1.3$  is estimated from this line. The corrected spectrum still does not represent the

true scaling of the global temperature, but it is a better representation than the periodogram of the original record.

### 5.3 Results for ice core time series

For the time series plots, time on the horizontal axis is given in years BP (before present), where “present” is defined as 1950 AD. The spectral analysis is presented in a double-logarithmic plot. The raw periodogram is plotted in gray, while the log-binned version is marked by black points. The spectral index  $\beta$  is estimated from the log-binned periodogram in the region shown by the blue line. Finally, the blue, shaded area indicate the 95% confidence range estimated from an ensemble of synthetic fGn’s/fBm’s with  $\beta$  and variance estimated from the log-binned periodogram. The plot of the wavelet scalogram is included in this section only for the GRIP Holocene/past 85 kyr record.

For the last glacial period, we present time series and periodograms for a time interval of  $\approx 80$  kyr. Spectral analysis results are also included for a combined Holocene/last glacial period time series from the GRIP ice core to illustrate that analysis of such records will be dominated by the glacial climate and suppress the characteristics of Holocene climate.

#### 5.3.1 Results from the GRIP ice core

Fig. 10a shows the  $\delta^{18}\text{O}$  time series of the Holocene part of the high-resolution GRIP ice core, and Fig. 10b the periodogram from the same time series. Fig. 10c displays the same time series as shown in (a), but with the earliest 2500 yr removed. Fig 10d shows the periodogram for the time series in (c). The rationale for removing the earliest part of the Holocene record can be seen from Fig. 10a, where one observes a decrease in  $\delta^{18}\text{O}$  around 8 kyr BP. This particular decrease is often observed in paleotemperature records from the northern hemisphere, and especially in records from the North-Atlantic region. The feature is known as the 8.2 kyr event, and the temperature change was probably caused by a large pulse of freshwater into the North-Atlantic Ocean associated with the collapse of the Laurentide ice sheet (Alley and Agustsdottir, 2005). In Fig. 10b,  $\beta$  is estimated to be  $\approx 0.3$  for time scales up to  $10^3$  yr. No scale break is detected on centennial time scales. The low value of  $\beta$  is typical for local temperature data from continental sites (Blender and Fraedrich, 2003; Fraedrich and Blender, 2003). On time scales longer than a millennium we can infer a higher  $\beta$ , but still  $\beta < 1$ . Since the 8.2 kyr event might affect the scaling we also analysed the shorter record (Fig. 10c). The periodogram for this time series is essentially flat. Fig. 11 shows the Mexican hat and Morlet wavelet scalograms for the full Holocene section of the GRIP ice core. The 8.2 kyr event clearly increases the power at millennial time scales, and this event is the source of the increased power observed at that time scale in Fig. 10b. From the periodogram of the Holocene part of the low-resolution GRIP time series we estimate  $\beta \approx 0.1$  (not shown in figure).

Lovejoy and Schertzer (2012b) claim that the paleotemperature records from Greenland ice core data are exceptionally stable for the Holocene period, and therefore downplay the significance of the

low scaling exponent and the absence of the scale break. This point of view is repeated in Lovejoy  
590 and Schertzer (2013), where an additional paleo sea surface temperature (SST) reconstruction is  
analyzed, (Berner et al., 2008). This SST reconstruction is based on diatoms from a marine sediment  
core sampled at Reykjanes Ridge in the western North Atlantic Ocean. Lovejoy and Schertzer (2013)  
find the spectral exponent  $\beta = 1.4$ . When we analyse the same data we find one single scaling regime  
and  $\beta = 1.1$ . There is nothing strange or exceptional in this land/sea difference. The same pattern of  
595 high/low spectral exponents are found for ocean/land surface temperature data for the instrumental  
period, see Fredriksen and Rypdal (2016) for spectral analyses of numerous instrumental, reanalysis,  
and GCM data sets. Figure 5 in that paper is particularly illustrative, as it shows that Reykjanes Ridge  
is located in a region with exceptionally high  $\beta$ .

Continuing the analysis of the GRIP paleotemperature record, Fig. 12a displays the  $\delta^{18}\text{O}$  time  
600 series from the last glacial period, and Fig. 12b the periodogram for the same time period. In Fig. 12a  
the Dansgaard-Oeschger (DO) events are observable as rapid warming over decadal time scales,  
followed by more gradual cooling (Bond and Lotti, 1995). In Fig. 12b we find  $\beta \approx 1.8$  for time  
scales longer than  $10^2$  yr and shorter than  $10^4$  yr. On centennial time scales and shorter, the spectrum  
is flatter. This means that a hypothesis of a scale break at centennial time scales is plausible under  
605 glacial climate conditions, even though such a scale break could not be identified from the Holocene  
time series. From the low-resolution GRIP data set we estimate  $\beta \approx 1.3$  for time scales longer than  
centennial, and a scale break is seen at this scale (figure not shown).

Fig. 13a shows the past 85 kyr time series of the high-resolution GRIP ice core, and Fig. 13b the  
periodogram for the same time series. In Fig. 13b,  $\beta \approx 1.6$  for time scales longer than centennial,  
610 and a scale break is visible at this scale. The periodogram in Fig. 13 is very similar to that in Fig. 12,  
indicating that the information from the Holocene is suppressed to a high degree in the periodogram  
of this time series.

### 5.3.2 Results from the EDC ice core

Fig. 14a shows the Holocene time series of the EDC ice core, and Fig. 14b the periodogram for the  
615 same time series. In Fig. 14a the Antarctic equivalent to the Northern Hemisphere Holocene climate  
optimum (HCO) occurred between 11500 and 9000 yr BP (Masson et al., 2000). In Fig. 14b,  $\beta \approx 0$   
for time scales shorter than  $10^3$  yr.

Fig. 15a shows the time series of the EDC ice core from the last glacial period, and Fig. 15b the  
periodogram for the same time period. We observe from the time series that the fluctuations do not  
620 coincide with the DO events in the GRIP ice core with respect to timing and amplitude. Like the  
glacial part of the GRIP ice core the EDC glacial time series Fig. 15a has higher fluctuation levels  
than the Holocene counterpart. In Fig. 15b we estimate  $\beta \approx 1.6$  for  $10^3 \text{ yr} < \tau < 10^4 \text{ yr}$ . The scale  
break in this figures appears at  $10^3$  yr.

## 6 Discussion and conclusions

625 In this paper we have examined a number of paleoclimatic temperature records to assess the feasibility of detection with confidence multiple scaling regimes in Holocene climate, and in particular a break in scaling around centennial time scales. Seven proxy/multiproxy reconstructions from the late Holocene, and one for the entire Holocene, have been selected for analysis due to high temporal resolution and coverage in time, and six reconstructions from deep ice cores sampled at Greenland  
630 and Antarctica also meet our requirements for temporal coverage and resolution.

For the seven late Holocene proxy-based temperature reconstructions, our first approach was to assume a break at exactly 100 years. Obviously there are few data points available for estimation on the longer scales using this procedure, and the estimated values of  $\beta_2$  are within the uncertainties of a mono-scaling model for all seven reconstructions. The scale break is therefore not statistically  
635 significant. For the second approach, our systematic procedure detects a break in scaling for all reconstructions. The time scale for the break varies significantly between reconstructions and is in most cases not even located near centennial time scales. The differences  $\beta_2 - \beta_1$  varies over a great range and takes on both positive and negative values. This procedure has also been tested on a Monte Carlo ensemble of fGn's and demonstrates that we will find such apparent breaks even in  
640 data that should not have breaks.

The discussion and correction of the temperature reconstruction by Marcott et al. (2013) illustrates the potential pitfall of uncritically selecting paleoclimatic time series for scaling analysis. The time series may be an excellent temperature reconstruction for many purposes, but for scaling analysis one needs to correct for the the fact that the data are increasingly low pass filtered as one goes  
645 backward in time.

From the analyses of the GRIP and EDC ice-core data, a scale break at centennial time scales is only observed in records from the last glacial period. Similar results are found for the analysis of four additional ice-core records presented in the supplementary material. The time series for the Holocene from the GRIP and EDC ice cores both exhibit weak persistent scaling (Figs. 10 and 14).  
650 The scaling exponent is estimated to  $\beta \approx 0.3$  and  $\beta \approx 0$  for the two ice cores respectively up to millenium time scale. No break in scaling can be observed at centennial time scale. The low value of  $\beta$  obtained is consistent with the scaling exponents observed over land from the paleoclimate model run presented in Blender et al. (2006). On time scales longer than millenial we do not have enough data points to make confident estimates of  $\beta$ . From the wavelet scalogram we argue that the increase  
655 in power seen at the longest time scales in the GRIP periodogram can be attributed to the 8.2 kyr event.

The scaling properties of the GRIP and EDC last glacial period are significantly different from the Holocene. A scale break at centennial time scales is identified with confidence from Figs. 12 and 15. We interpret this scale break as being associated with the variability of Dansgaard-Oeschger events  
660 and teleconnections to the Southern Hemisphere, (WAIS Divide Project Members, 2015). A number

of theories and models exist for the mechanism of these events, see e.g., Dokken et al. (2013). **That study indicates** that the DO-variability is internal and not a direct response to external forcing.

From the GRIP time series including both the Holocene period and the last glacial period we obtain a power spectrum very similar to that of the glacial climate, Fig. 13. **Because the durations of the late Quaternary interglacials are generally much shorter than for the glacials, the Holocene temperature variability is strongly suppressed when time series covering 100 kyr or longer are used to estimate scaling exponents.** Our analyses of Holocene records, on the other hand, show that a scale break on centennial time scales is not a universal feature, and in those cases it appears to be present, it cannot be detected with sufficient certainty.

The DO events are observed exclusively in records from the glacial climate state, but a number of studies investigate the possibility of cyclic climate variability on millennial time scales also in the Holocene. Bond et al. (1997) presents paleoclimatic data from different sources, indicating a number of cooling events throughout the Holocene related to ice-rafting in the North Atlantic Ocean. The Little Ice Age, the 8.2 kyr event and even the Younger Dryas are examples of cold periods sometimes denoted “Bond-events”. The amplitudes of the temperature anomalies are much smaller than for the DO events, but Bond et al. (1997) find the periodicity to be similar ( $1470 \pm 352$  yr, the “Bond-cycle”). From these results, the authors infer a pervasive quasiperiodic climate cycle occurring independently of the climate state. The majority of the data indicating Holocene cooling events is from marine sites, and the proxies are in most cases not that sensitive to temperature. Therefore, in the data we have analysed, the evidence for cooling events is essentially limited to the 8.2 kyr event (GRIP) and the LIA (multiproxy reconstructions). If we assume that the DO events cause the characteristic scale break observed in the power spectra at centennial time scale during glacial time periods, should we also expect the Bond events to manifest themselves in the spectra from the Holocene? It is clear from our results that one event in each record is not sufficient to cause a scale break at centennial time scales, but higher power on millennial time scales is possible. The uncertainty due to finite-size effects does not let us draw firm conclusions about the scaling on these time scales.

The idea of a millennial climate cycle, which may have some manifestation even in the Holocene, relates well with the recent results by Rypdal and Rypdal (2015). In this study, the background temperature variability (the climate noise) during the late Quaternary is found to follow a monoscaling power law of  $1/f$ -type when DO events and glacial/interglacial transitions are excluded from the analysis. The glacial/interglacial changes are driven by orbital forcing, while the origin of the 1470-year climate cycle is debated and unclear at present. Removing temperature variability related to the Bond cycles for the Holocene may prove an effective way to obtain the proposed  $1/f$  background climate noise. However, it should be mentioned that the very existence of the Bond-cycles is debated. Chronological uncertainties in the proxy data, spatial conformity and undersampling of proxy records are unsettled issues.

Faced with the results we have presented here one may ask what the practical implications are. Is scaling in climatic time series a useful concept? Our perception is that a scaling law may be useful as a statistical (stochastic) model when a causal description turns out to be very complex, i.e., when the viable alternative is something like a general circulation model. Such a statistical model does not have to exhibit long-memory scaling (a more standard model is a short-memory autoregressive process). Nevertheless, there is strong evidence, for internal variability of surface temperature data, that an fGn is a much better model than an AR(1) process for time scales at least up to centuries (Rypdal and Rypdal, 2014). Thus, for prediction on time scales up to decades, a single-regime mono-scaling model with  $\beta < 1$  is what should be used (Lovejoy et al., 2015). More interesting, however, is whether long-memory scaling is important for prediction on century time scales and beyond, and here the issue of non-stationary scaling ( $\beta > 1$ ) for such time scales becomes crucial. What is the proper value of  $\beta$  to use in such prediction efforts in a warming Holocene climate? The conclusion we draw from our results is that, unless we ignore the knowledge that the present climate state of the Earth is an interglacial, we should still use  $\beta < 1$ . One argument that can be raised against that conclusion is that, even though we cannot reject the hypothesis of single-regime scaling based on available Holocene data, we cannot exclude that two scaling regimes is true either. Moreover, the latter is supported from records spanning hundreds of kyr which encompass both glacial and interglacial climate. This stalemate reflects that we are faced with a model selection problem where the outcome depends on which available knowledge we prefer to emphasize.

The multiple regime model stresses the information we have on scaling in the second-order statistics such as power spectra ( $\beta > 1$ ) on time scales up to hundreds of kyr (Quaternary scaling), and infers that this scaling should be a guideline for prediction independent of whether the initial state is glacial or interglacial. It essentially ignores the fact that Quaternary climate is characterised by several intermittencies (Lovejoy and Schertzer, 2012b). One type of intermittency implies that the probability density functions (PDFs) are heavy-tailed on short time scales and approach Gaussian on longer time scales. This typically happens if the signal is bursty, but without long-range correlation between bursts. In this case the high-order structure functions are not straight lines in a log-log plot. Another, and more restricted, class of intermittent processes are those that are multifractal. Here we have correlated bursts, straight structure functions, but curved scaling function. Hence structure functions of higher order than two are needed to characterise the process. For a Gaussian process the power spectral density can be inferred from the second-order structure function and hence does not convey information beyond second-order statistics. Moreover, Quaternary climate is characterised by the glacial-interglacial transitions, which adds more intermittency, and all this intermittency makes prediction based only on Quaternary scaling very difficult.

The single-regime model, on the other hand, ignores the information available on time scales beyond the Holocene, but makes use of the fact that our present climate state is an interglacial, and that second-order statistics is sufficient to describe the scaling on the time-scales that is available to

us in the Holocene. As discussed above, and by Rypdal and Rypdal (2015), single-regime scaling  
735 can be rejected by data that goes way beyond the Holocene if this scaling is supposed to account  
for DO-events and glacial/interglacial transitions, but there is no statistically significant empirical  
evidence that the scaling inferred by glacial-state data is present in the interglacial climate state.

The issue discussed in this paper is an example of a more general problem concerning scaling  
analysis that needs to be addressed in a systematic manner. On geological time scales the Earth is an  
740 evolving system. There are cycles, but the Earth rarely repeats itself. The Eemian was similar to the  
Holocene, but also very different. **One striking difference being the evolution of human civilisations  
and the resulting anthropogenic climate forcing.** Thus, the dynamics of the Earth is non-stationary  
in a very fundamental sense. This makes scaling analysis, and modelling of Earth processes based  
on such analysis, a quite problematic issue. It has little meaning to talk about a universal scaling in  
745 Earths climate since the scaling characteristic on a given range of scales up to a chosen maximal  
scale  $\tau_{\max}$  will depend on the eon, era, period, epoch, or age the analysis is done. In other words, the  
result will depend on the time  $t$  around which the time range  $\tau_{\max}$  is centred. A scaling analysis of  
a given Earth-system variable must therefore be conditioned by two essential parameters; the range  
 $\tau_{\max}$  of scales considered, and the positioning  $t$  of this range in time. The time series and the wavelet  
750 scalogram of the GRIP temperature series for the past  $t_{\max} = 90$  kyr illustrates the issue, as shown in  
Fig. 16. The central time parameter  $t$  is along the horizontal axis and the scale  $\tau$  along the vertical.  
We have no data for the future, which means that the transform cannot be computed correctly above  
the upper white line in the figure. Likewise, the area below the lower white curve is influenced by  
the interpolation made due to uneven sampling of the time series. It is apparent that the scalogram  
755 is different in the first 11.5 kyr (the Holocene) from the remaining 80 kyr (the last glacial). There is  
generally lower power on all scales in the Holocene, and the increase in power with increasing scale  
as  $t$  is kept constant is lower. We can also observe from this scalogram that the longest interstadials  
(warm stages) associated with DO-events exhibit variability very similar to the Holocene.

The literature reveals that there is no consensus of how this issue of non-stationarity could be  
760 handled. Ice cores restrict the information we can obtain to somewhat less than  $\tau_{\max} = 1$  Myr BP.  
This is the range of time scales considered in the work of Lovejoy and Schertzer (2012b), and the  
period is the Quaternary in which the Earth's climate has been in a bistable state shifting between  
glacials and interglacials. The methodology and interpretations are based on this choice of the pa-  
rameters  $(\tau_{\max}, t)$ . We don't see anything wrong with that, as long as one is mindful on that this is  
765 a choice, and recognizes that there are other, equally valid, choices. If the issue is understanding of  
the present and future climate in our present interglacial state, we don't believe this choice is useful,  
simply because it ignores the knowledge that the Earth at present resides in an interglacial state and  
probably will continue to do so as long as there is human civilization and anthropogenic forcing on  
this planet.

770 The issues dealt with in this paper reveals that a debate on the role of statistical hypothesis test-  
ing and scientific method in general is unavoidable if scaling analysis is going to be accepted as a  
useful method in climate science. Our main statement is that it is scientifically incorrect to draw pos-  
itive conclusions about an alternative hypothesis (two scaling regimes) from finite size data sets that  
do not allow rejection of a plausible null hypothesis. This null hypothesis involves a single scaling  
775 regime with some distinct events or oscillations superimposed, raising the power on millennial time  
scale. We do not claim that the scale-break hypothesis is false, but we claim that the null hypothesis  
cannot be rejected from the data at hand. The distinction between the two hypotheses might seem  
unimportant, but it is not, because the important issue is the nature of the fluctuations on time scales  
longer than a few centuries. The scale-break hypothesis states that these fluctuations are scaling.  
780 We contend that the data do not reject the null hypothesis that these fluctuations are of quite differ-  
ent nature, and hence that claimed scaling properties on these long time scales cannot be used for  
understanding or prediction of Holocene climate.

In [Lovejoy and Schertzer \(2012b\)](#); [Lovejoy et al. \(2013\)](#) the two-regime scaling hypothesis is pre-  
sented as one that has been tested against data. In any precise meaning of the concept of hypothesis  
785 testing, this implies that other plausible descriptions of the observations have been rejected. By pre-  
senting the evidence this way these papers run a great risk of committing a Type-I statistical error (a  
false positive). If the present paper had claimed that this hypothesis is false we would have run the  
same risk of committing a Type-II error (a false negative). But this is not what we have done here.  
Our conclusion is that the issue of scaling beyond centennial time scales is still open, in spite of the  
790 large body of literature that conveys the impression that it is closed.

*Acknowledgements.* This paper was supported by the the Norwegian Research Council (KLIMAFORSK pro-  
gramme) under grant no. 229754. We are grateful for discussions with Martin Rypdal and Dmitry Divine,  
technical assistance from Ola Løvsetten and Peter Ditlevsen for providing the high-resolution GRIP data set.

Neukom et al. 2014	0.5	0.8	9	0.3

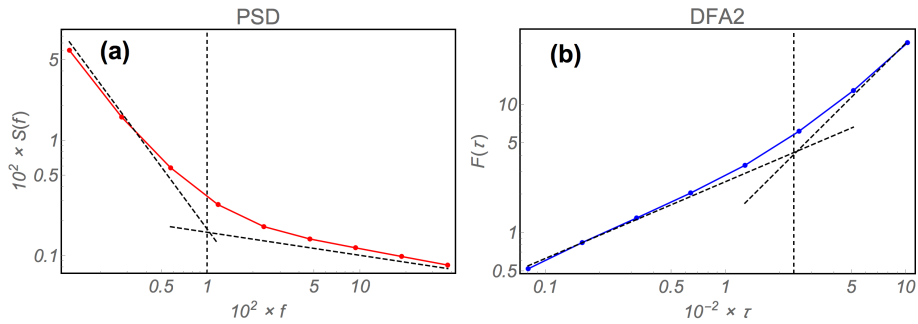

**Figure 1.** (a): Structure function estimates (empirical moments)  $\hat{S}_q(\Delta t) = (N - \Delta t)^{-1} \sum_{i=1}^{N-\Delta t} |T(t_i + \Delta t) - T(t_i)|^q$  for the GMST (HadCRUT3) monthly record 1880-2010;  $T(t_i)$ ;  $i = 1, \dots, N$ . (b): Structure function for the cumulative sum  $y_{t_i} = \sum_{j=1}^i T(t_j)$ . (c): Structure function for the cumulative sum of the quadratically detrended GMST. (d): Scaling functions for the undetrended cumulative sum (upper line) and the detrended cumulative sum (lower line).

**Figure 2.** (a): The instrumental global mean surface temperature (GMST) 1850 – 2010 (black). A second order polynomial least-square fit to the GMST record (blue). (b): Black curves are the Haar fluctuation function of the GMST, the upper is multiplied by 10. The red curves are Haar fluctuation functions of 20 realizations of a model comprised of a linear combination of an fGn with  $\beta = 0.8$  and an fBm with  $\beta = 1.6$ . The blue curves are the same of a model comprised of a linear combination of an fGn with  $\beta = 0.8$  and the second-order polynomial trend.

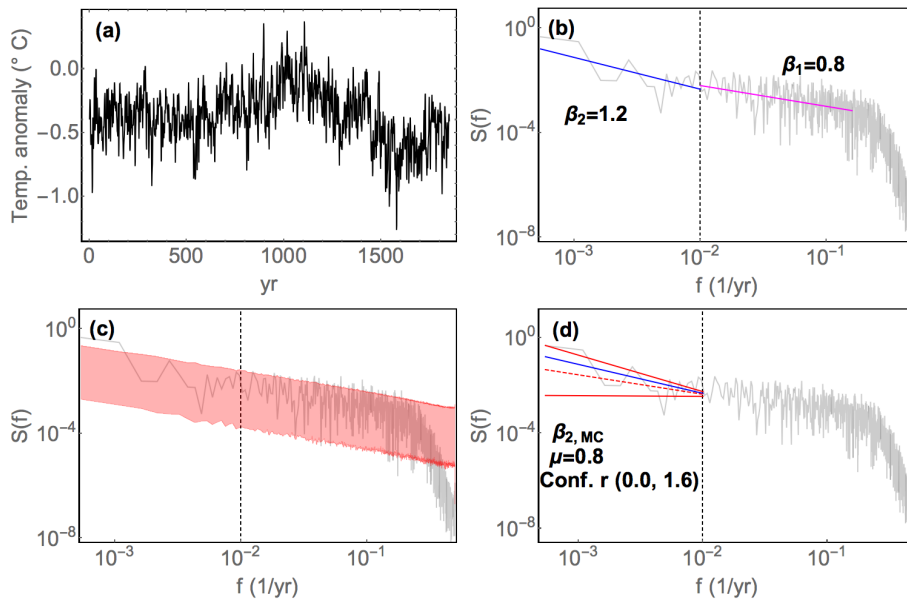

**Figure 3.** (a) The Haar fluctuation of 20 realisations of an fGn with  $\beta = 0.8$ . (b) The Haar-fluctuation of one realisation in the ensemble. (c) The Haar wavelet variance of the same 20 realizations as in panel (a). (d) The Haar wavelet variance of the same realisation as in panel (b).

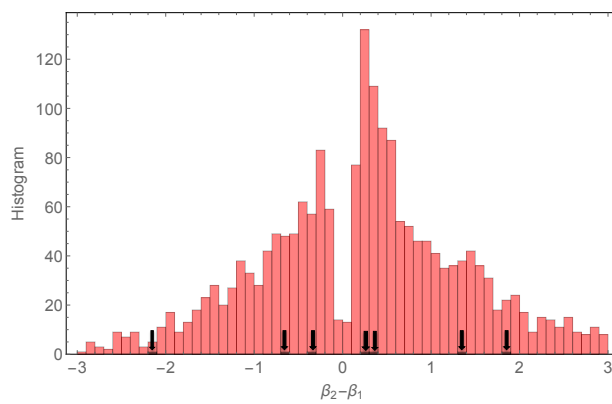

**Figure 4.** (a) The power spectral density of an ensemble mean of synthetic processes comprised of a superposition of a white noise ( $\beta = 0.2$ ) and a Brownian motion ( $\beta = 1.8$ ). (b) DFA fluctuation function  $F_2(\tau)$  for ensemble mean of the same process. The dashed lines are the limiting slopes at short/long scales. Their intersection is used to define a transition frequency (vertical dashed line) between the two scaling regimes in (a) and a transition scale for the DFA in (b).

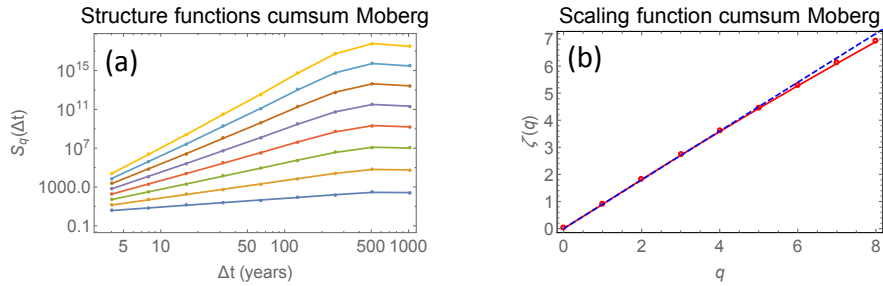

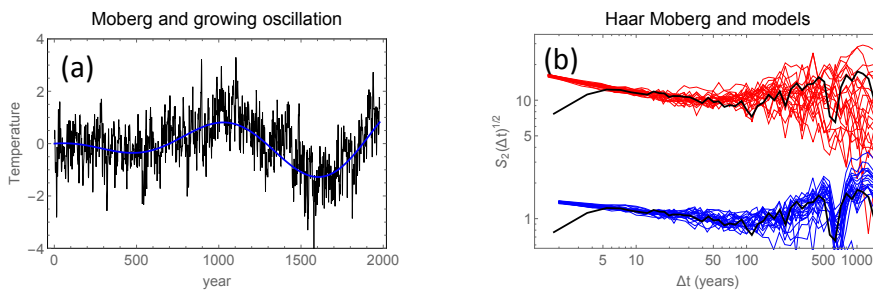

**Figure 5.** a) The Moberg et al. (2005) reconstructed temperature for the Northern hemisphere. (b) Estimated values of  $\beta_1$  and  $\beta_2$ . (c) 95% confidence range for periodograms in Monte Carlo study. (d) 95% confidence range for estimates of  $\beta_2$ .

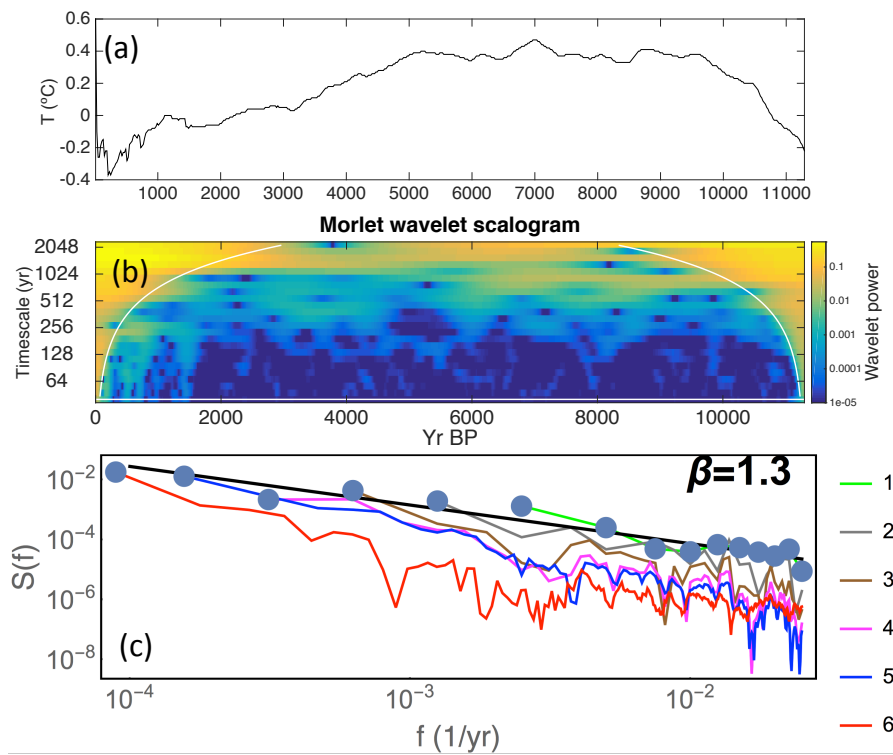

**Figure 6.** Differences in  $\beta_2$  and  $\beta_1$  for a Monte Carlo ensemble with 2000 members of synthetic LRM processes with  $\beta=0.7$ . The black arrows indicate the differences from the multiproxy reconstructions.

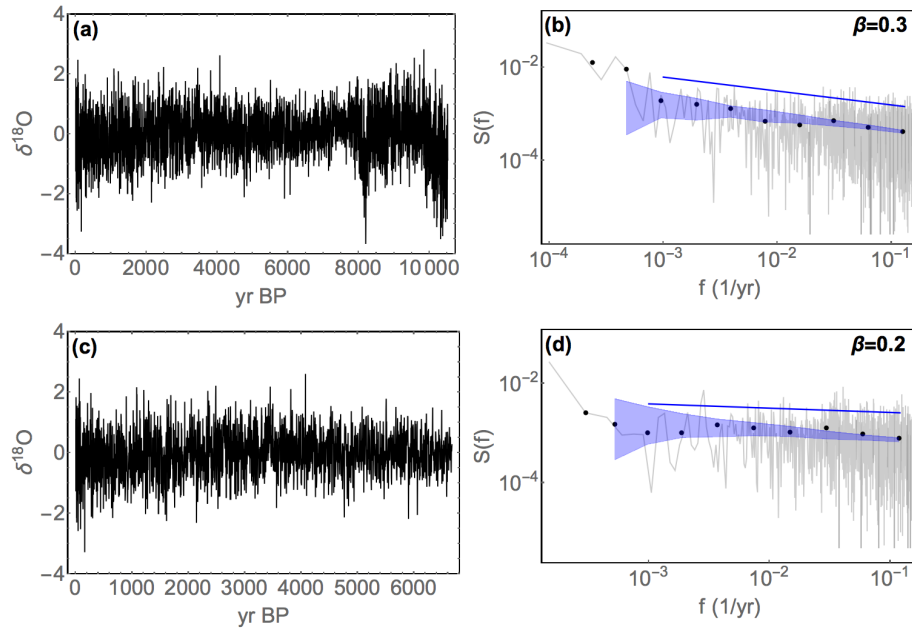

**Figure 7.** (a): Structure functions for the cumulative sum of the Moberg NH reconstruction year 0–1979. (b): Scaling functions for the cumulative sum computed from straight line fits to the SFs in the scale range 1 – 500 yr.

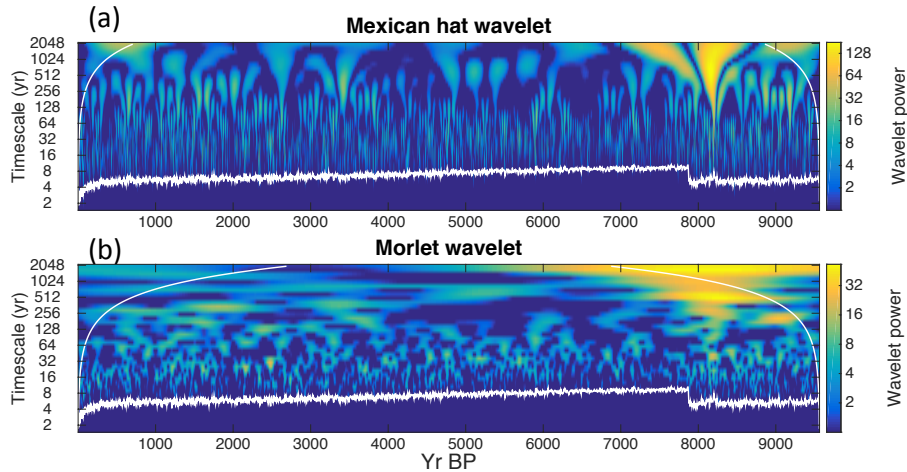

**Figure 8.** (a): The Moberg reconstruction (black). A fit of the function  $A t \sin[\omega(t - \varphi)]$  (blue). (b): Black curves are the Haar fluctuation function of the Moberg record, the upper is multiplied by 10. The red curves are Haar fluctuation functions of 20 realisations of a model comprised of a linear combination of an fGn with  $\beta = 0.6$  and an fBm with  $\beta = 1.6$ . The blue curves are the same of a model comprised of a linear combination of an fGn with  $\beta = 0.6$  and the trend  $A t \sin[\omega(t - \varphi)]$ .

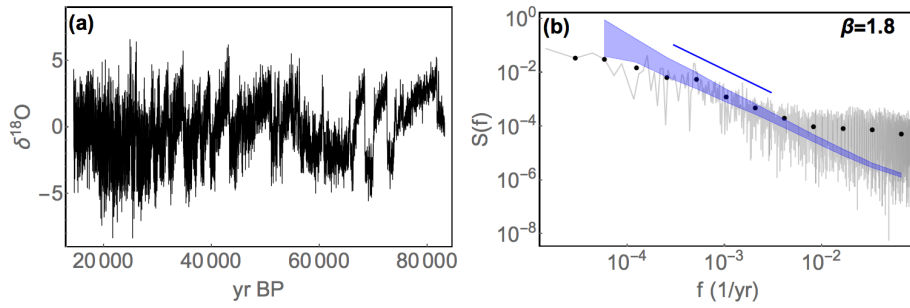

**Figure 9.** (a) The reconstructed time series covering the entire Holocene time period. (b) Wavelet scalogram for the same time period. (c) Section 1-6 of the reconstruction described in section 5.2, and composite spectrum (black line, blue dots). The estimated  $\beta$  is estimated for this line.

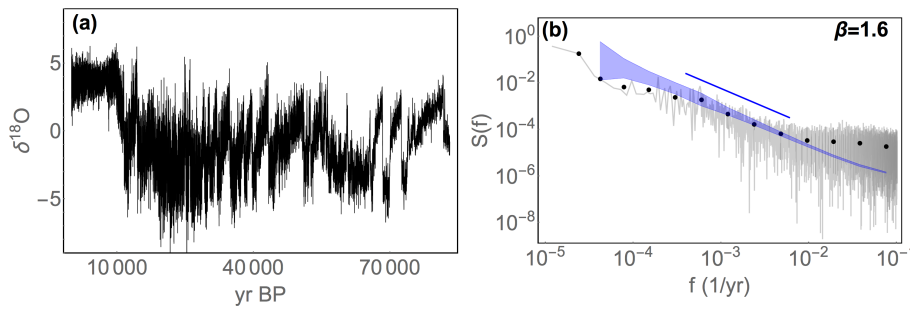

**Figure 10.** (a):  $\delta^{18}\text{O}$  anomalies from the Holocene part of the high-resolution GRIP ice core. (b): Periodogram. The raw periodogram is shown in gray, the log-binned version by black dots.  $\beta$  is estimated from the log-binned periodogram in the region marked by the blue line. The confidence range is shown by the blue, shaded area, estimated from a Monte Carlo ensemble of synthetic fGns with the estimated value of  $\beta$  and variance from the log-binned periodogram. (c) Same figure as in (a) except the oldest section has been removed. (d) Periodogram for the time series in (c).

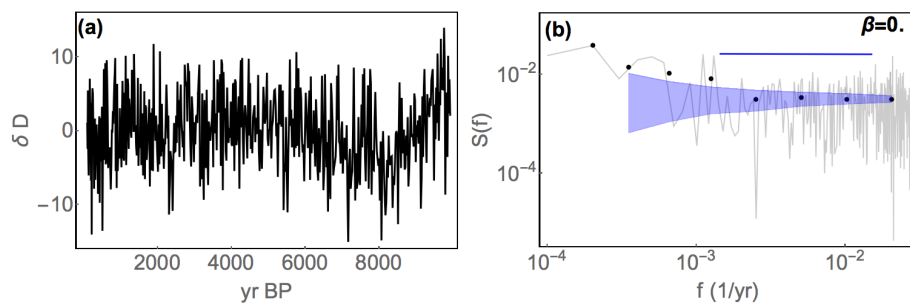

**Figure 11.** Top: the Mexican hat wavelet scalogram for the Holocene part of the GRIP ice core, and bottom: the Morlet wavelet scalogram for the same time series. The lower white curve in each plot denotes the varying Nyquist frequency, and the upper white curve the area affected by edge effects. Studies are restricted to the area between the two curves. The color bar to the right of the figure is used to indicate the the magnitude of the wavelet power.

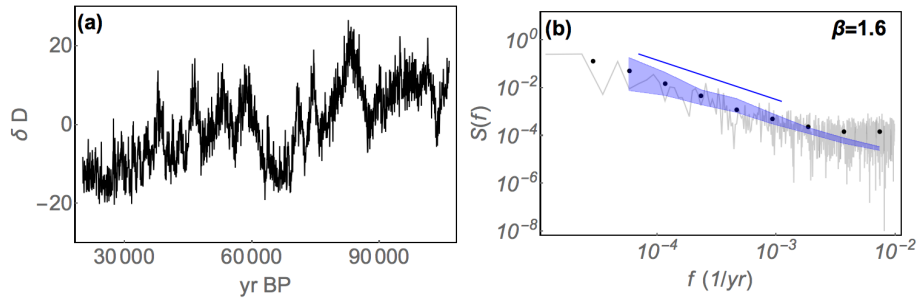

**Figure 12.** (a):  $\delta^{18}\text{O}$  anomaly time series from the last glacial period of the high-resolution GRIP ice core. (b): Periodogram for the time series in (a).

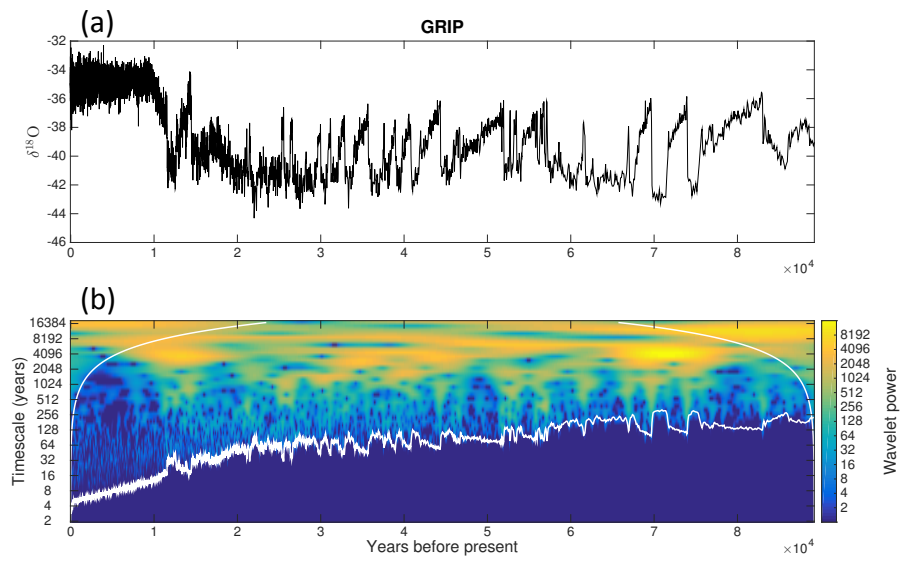

**Figure 13.** (a):  $\delta^{18}\text{O}$  anomalies from the past 85 kyr of the high-resolution GRIP ice core. (b): Periodogram for the same time series.

**Figure 14.** (a):  $\delta\text{D}$  anomalies from the Holocene part of the EDC ice core. (b): Periodogram.

**Figure 15.** (a):  $\delta D$  anomalies from the last glacial period part of the EDC ice core. (b): Periodogram for the time series in (a).

**Figure 16.** Upper panel: The  $\delta^{18}\text{O}$  proxy time series for Greenland temperature from the GRIP ice core for the period 0 – 90 kyr BP. Lower panel: The Morlet wavelet scalogram for the signal in the upper panel.
