This file contains our point-to-point response to review comments (Part 1) and our revised manuscript with tracked-changes (Part 2).

Part 1: Response to reviewer's comments

We deeply thank the two reviewers for their time and helpful, important comments. Below is our point-to-point response to each comment. The original comments are in bold, our responses are in regular font and relevant changes in text are in italic font.

Anonymous Referee #1
Received and published: 30 October 2015
Dear Authors,
I congratulate you to this paper which elegantly addresses many aspects of deforestation-induced climate change such as local versus remote effects of deforestation, the nonlinear dependence of the magnitude of change on the scale of deforestation, a decomposition of the total change into contributions from the three most im-portant biophysical factors, and an explanation of the latitudinal change signal in terms of background climate conditions. I only have some minor suggestions, questions and technical corrections.

Thanks for your favorable comments.

p1899l20–23 "Further analysis [. . .]": I do not really understand this sentence. Surely, it can be written more intelligibly.

This sentence has been revised:
"Our analysis reveals that the latitudinal temperature change largely results from the climate conditions in which deforestation occurs, and is less influenced by the magnitude of individual biophysical changes such as albedo, roughness, and evapotranspiration efficiency."

p1903l3–6 So VEGAS does calculate a land surface albedo. Why don't you use these data directly? Are the albedo changes calculated by VEGAS used as is, I mean, don't they need to be adjusted (rescaled maybe) to the corresponding satellite observations?

Yes, VEGAS does calculate vegetation albedo (Av), by using a simple empirical formula as a function of LAI:

$$A_v = A_{min} + (A_{max} - A_{min})\exp(-k\ L)$$

where Amin = 0.1 and Amax = 0.45 are the minimum and maximum albedo, respectively, and k = 0.5 is the light extinction coefficient. Here is a detailed explanation on this issue provided by (Zeng & Yoon, 2009): "This simple empirical formula is not sufficient at capturing all the possible processes responsible for the observed albedo, many of which are difficult to model mechanistically at present. For instance, bright deserts with high albedo values often correspond to sand dunes or dry lake beds whose formations are also related to other hydrogeological processes [Knorr and Schnitzler, 2006]. To minimize potential climate drift due to full coupling, only the anomalies A'_v (changes in A_v relative to a control run) are used by the atmospheric radiation module, i.e., the changes in A_v was added onto the observed surface albedo climatology in order to capture the first-order effects due to vegetation change"

$$A = A_{obs} + A'_v$$

And the following explanation words has been added to the text:
"*Vegetation-albedo feedback is treated in the model by introducing albedo anomalies. This procedure sums the albedo change due to vegetation change (calculated by VEGAS using an empirical formula as a function of leaf area index (LAI)), and the observed albedo climatology used by the atmospheric radiation module (Zeng & Yoon, 2009). This albedo anomalies treatment prioritizes the capture of the first-order effects of albedo change due to vegetation change, since many of the possible processes that are responsible for the observed albedo are difficult to model mechanistically.*"

p1903l25–27 Please briefly discuss the limitations this entails. For example, would your results change much if you used a perpetual 30-year (1960–1990) cycle of SST observations? Please also state which SST data you used.

SST data are from HadSST and we have revised the sentence to include this information.
"The model is driven by a climatological seasonal cycle of SST derived from HadSST (Rayner et al., 2006), averaged over 1960–1990 to smooth the influence of inter-annual climate variability."

We also added the following content to discussion regarding to the choice of SST climatology.
"In the simulation, we used the SST climatology of 1960-1990 with seasonal cycle only that can minimize inter-annual variability and therefore amplify the strength of deforestation signal to climate variability in terms of statistical significance. If a different period of the SST climatology had been used, the simulated climate may have been slightly different including differences in vegetation distribution and deforestation impacts. Nevertheless, our results are unlikely to be substantially changed by the choice of SST climatology, because a background climate change as large as that coming from 1× CO2 (280 ppm) increased to 2×CO2 (280 ppm) can only modify the climate impact over certain transitional regions (Pitman et al., 2011)."

p1904l3–5 This part is not well written. Please polish. Also, I think you should include some observational precipitation data for comparison in Fig. S2. I mean, you allude to the possibly detrimental impact of precipitation biases on the quality of simulated PFT distributions but then it appears as if you tried to get away from this issue as quickly as possible. Please address the issue briefly but properly.

The idea of comparing the simulated precipitation with observation data is very needed for many cases but it may not very necessary in our case because there are issues for such comparison.

First, bias in simulated climate is expected for a model with intermediate complexity. Therefore, the bias, if any, is tolerable for our experiment because we mainly focus on the climate response to vegetation change as well as its mechanisms rather than accurately reproducing historical or future climate change. Second, what we designed is an idealized experiment, for example, using preindustrial CO2 and seasonal SST data. Strictly speaking, the simulated climate is not comparable to the observed climate in the real world. Due to these fundamental differences, a direct comparison with observations could be problematic and give little help to the paper.

We added above explanation to the text:
"The vegetation map generally has a reasonable geographical distribution but does not perfectly match modern vegetation of the real world. This is expected because the potential vegetation is derived from an equilibrium state with climate. Therefore, any differences in the simulated climate compared to modern climate or any simulation bias, for example, in precipitation (Figure S2), could influence the vegetation distribution. In addition, some bias in simulated climate is expected for a model with intermediate complexity. Such bias is tolerable in our experiments due to the focus on the climate response to vegetation change and its mechanisms as opposed to an accurate reproduction of historical climate change."

p1904l10–12 What would happen if you replaced the forest by grass? Wouldn't that be the more realistic change? Please at least briefly address this point in the discussion section.
Replacing forest by grass or crop is also a common practice for deforestation experiment in the literature. Compared to the forest-to-bare conversion, the conversion to grass/crop often leads to smaller biophysical changes in albedo and roughness, thus it is expected to have similar but smaller impact.

We added a new discussion to the text for this issue.
"An alternative strategy of implementing deforestation experiment is to replace trees with grass (crop). This is considered to be more "realistic" than replacing trees with bare ground (Davin & de Noblet-Ducoudré, 2010). The conversion of trees to grass is expected to induce a similar but less pronounced impact on climate (Gibbard et al., 2005), compared to the conversion of trees to bare ground which would represent the maximum impact of deforestation. Despite this difference, both strategies are frequently used in existing literature to represent deforestation, and they yield consistent findings as the operating mechanisms and feedbacks are the same."

p1906l6–7 Polish your English here, please.

We revised the text:
"The deforestation impact in the simulation is a very strong signal relative to the small inter-annual variability, making almost all changes over the land statistically significant. For this reason, significance levels are not shown on the map."

p1906l21 Precipitation in W/m2: Please use a more common unit throughout the manuscript or specify the equivalent of 1 W/m2 in a more common unit such as mm/day at first mention.
Thanks for this suggestion. In the revision, we have changed the unit of precipitation to mm/day for all relevant texts, tables and figures.

p1908l2–3 "despite different spatial scales": I don't understand. . .

We revised this sentence to:
"Overall, an amplified temperature change in the global deforestation experiment is expected as it generates a stronger perturbation to the atmosphere, but the latitudinal temperature response is well preserved despite the spatial extent of deforestation increases from regional to global level."

p1908l14–16 Please write this more clearly.
We revise the sentence and provide an additional Figure S6 (using albedo change as a example) to show the non-linearity of the temperature response to deforestation can either arise from the response of biophysical land parameters to deforestation or from the climate response (i.e., temperature response) to biophysical changes.

Relevant changes in text are:
"This nonlinearity can either arise from the response of biophysical land parameters to deforestation, or from the climate response (i.e., temperature response) to biophysical changes. We found nonlinearities in both of these aspects (Figure S6)."

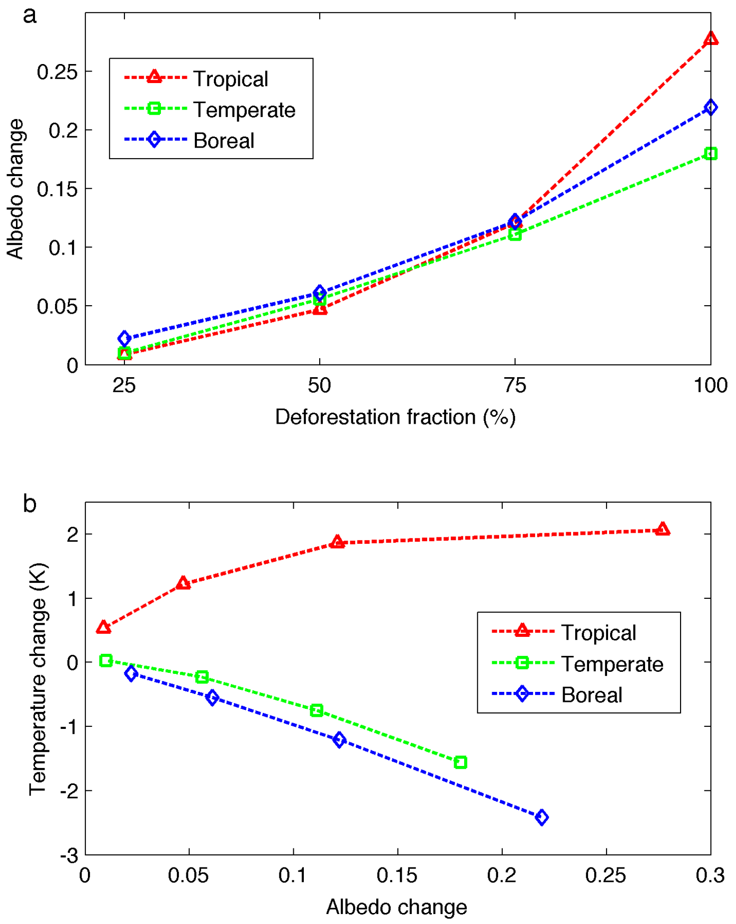

Figure S6 (a) Response of albedo change to growing deforestation fraction from 25% to 100% and (b) temperature response to albedo change under different deforestation fractions. Data points in the figure are from Table 3.

p1910l1 "when ΔH is considered": I suggest to refer to Tab. 2 once again, here.
We have taken this suggestion in the revision.

p1911l11 Shouldn't you better specify the albedo changes in percent, just as you do for ET?!

Here we want to demonstrate that a given percentage of change in shortwave radiation and ET can lead to the latitudinal pattern in ΔSW and ΔET as a result of background climate. So we use background incoming shortwave radiation and ET for the calculation, multiplied by the percent of change, expressed by albedo and ET reduction rate respectively. In fact, the absolute albedo change itself denotes shortwave change in percent, which is essentially similar to ET reduction rate.

In this calculation we assume changes in absorbed shortwave radiation at surface are solely induced by albedo change. In this case, changes in absorbed shortwave radiation (ΔSW) are:
ΔSW=(SW1¯-SW1↑)- (SW0¯-SW0↑)
“0”: before change; “1”: after change
And albedo by definition is given by alb=SW↑/SW¯
Since there is no change in SW¯ by assumption, SW1¯= SW0¯
Therefore,
ΔSW=SW0↑-SW1↑=alb0*SW0¯- alb1*SW1¯=(alb0-alb1)*SW0¯.
This equation indicates that changes in absorbed shortwave radiation (ΔSW) can be calculated by background SW multiplied by albedo change.

p1913l10–12 “[. . .] in the tropical region (Table 4) where its effect on climate can be isolated [. . .]”: This holds everywhere, not just in tropical regions, right? Please rephrase.
Thank you for pointing this issue, the sentence has been revised as:
“Effect of roughness on climate can be isolated by the difference All – noRGH. Roughness change as well as its impact are more pronounced in the tropical region (Table 4).”

p1913l16–18 I guess you mean that even if deforestation was not associated with rough- ness change, some parts of the tropics would warm because the reduction in evapotranspiration efficiency would still outweigh the albedo impact in those parts. I don’t know how clear you will find this statement but you should definitly rephrase your version.
Yes, that is exactly what it means. We revised the sentence to explain it more clearly:
“Moreover, Figure 8b also shows the combined effects from albedo and evapotranspiration efficiency since roughness effect is excluded. Thus, the existence of a tropical warming in some regions implies that the reduction in evapotranspiration efficiency remains dominant and outweighs the albedo impact in this situation.”

p1913l23 “Lower ET” → okay “and higher sensible heat” → not necessarily as you show in Tab. 2.
The original sentence has been revised as:
“The conversion of forest to bare land favors more turbulence energy to be transferred in the form of sensible heat rather than ET, resulting in higher Bowen ratio.”

p1914l22 "perhaps": You don't need to be so cautious here, do you; doesn't Sect. 3.4 strongly support this statement?
This is done as suggested.

Tab. 2 The caption is not entirely precise. I assume the Δ values of a column refer to averages over the respective latitudinal band specified in the top row? Are these land surface variables? (These two questions also pertain to Tab. 3.) What exactly are the turbulent flux and the available energy?

Caption of Table 2 has been revised to clarify these issues and turbulent flux and the available energy are explained in the table. Similar changes are also made to Table 3.

Revised caption for Table 2:
"Table 2 Changes in key climate variables from regional and global deforestation experiments. "Δ" denotes change relative to the control experiment and value for each climate variable is the area-weighed changes over deforested areas for different latitude zones. The symbol "↑" denotes upward and "↓" denotes downward. Units are W/m2 for energy flux, K for temperature, mm/day for precipitation, and unitless for albedo."

Revised caption for Table 3:
"Table 3 Changes in key climate variables from global deforestation with different deforestation fractions. "Δ" denotes change relative to the control experiment and value for each climate variable is the area-weighed changes over deforested areas for different latitude zones. The symbol "↑" denotes upward and "↓" denotes downward. Units are W/m2 for energy flux, K for temperature, mm/day for precipitation, and unitless for albedo."

Moreover, I wonder why there is a difference in Δalbedo between regional and global deforestation scenario runs. Where does this come from?
Yes, there is slight difference for Δalbedo between regional and global deforestation experiment over the same region. This difference is very small indeed, ~0.01 or less, see Table below. And we have changed the unit for Δalbedo in Table 2 and 3 from percentage to absolute change and redo the rounding.

Surface Albedo change	Regional Deforestation	Global deforestation	Difference
Tropical	0.264418	0.276663	-0.0122
Temperate	0.169792	0.179784	-0.0100
Boreal	0.217404	0.218868	-0.0015

We are not sure about the exact reason for this difference. We list some possible causes.
(1) Rounding error.
(2) ΔAlbedo induced by vegetation change is the same between regional and global deforestation experiment before it is passed to atmosphere model for radiation calculation.

There might be some other processes (not surface albedo) that lead to the slight differences in the climate response between regional and global deforestation experiments that can also influence shortwave radiation (e.g., relating to scale extent). Because albedo shown in the table is calculated by SW↑/SW¯, therefore, a tiny difference in SW↑ or SW¯ between regional and global deforestation experiment can result in a difference in Δalbedo.

Fig. 6 Why do you show the solid curves for all four deforestation fractions? If I understand the corresponding part in the text correctly, then the curves are just scaled versions of one and the same curve in all subplots, so it would suffice to show only subplot (d). (Okay, I see that the relative changes of ET and SW differ from fraction to fraction. Well, your choice whether to leave it as is or not.)

Four subplots in Fig. 6 show the calculated ΔSW and ΔET with different combinations of ET reduction rate and albedo change. We want to retain these four calculated scenarios because they indicate the good correspondence between calculated and simulated ΔSW and ΔET are not coincidence from a single parameter combination.

We revised caption of Fig 6.
"Figure 6. The latitudinal pattern of ΔSW and ΔET calculated by multiplying their background climate values with different rates for albedo (red number, from 0.02 in (a) to 0.23 in (d)) and ET changes (blue number, from -15% in (a) to -75% in (d)). In (d), dashed lines are simulated changes from global deforestation for comparison with the calculated changes (solid line)."

2 Technical corrections

p1902l18–23 Please explain all the abbreviations in the model names.
Done as suggested.

p1913l2 does → did
Done as suggested.

p1917l7 Could you please give a reference for LUMIP.
We Added the website for LUMIP (https://cmip.ucar.edu/lumip), since there hasn't been any papers published yet.

Fig. 4a Please append a ↓ to ΔLW in the figure legend.
It has been corrected.

Fig. 5 Where you write (e, f) in the caption I guess you mean (d–f).
It has been corrected.

Fig. S2 Wrong unit, I suppose. Fig. S5 Unit missing.
We changed unit for Fig. S2 to mm/day.
And we added unit (m) into caption for Fig. S5.

Moreover, in all map plots, the grid cells seem to be shifted relative to the coastlines by one or at least half a grid cell (certainly for the longitudes, maybe also for the latitudes). Please fix that.
Thanks for pointing out this latitude shift issue. We replace all spatial figures with this issue solved in the revision (see these figures in the revised manuscript).

Anonymous Referee #2

In this manuscript the authors simulate hypothetical deforestation scenarios with an intermediate complexity Earth system model. The then investigate the resulting temperature changes and the mechanisms that cause these, all with a special focus on the latitudinal dependencies. The authors use fixed SST and CO2 contents from 1960..1990.
Overall I find the paper worthwhile and a nice contribution to climate sciences. I would have prefered a more thorough discussion of the state of the art of this topic, and also a little bit more contrasting of the results to other studies. On the second point: The authors explain convincingly, why they can't do this, though. I like the idea of disentangling the various contributions to the overall temperature change effect. The manuscript doesn't provide anything groudbreaking new, but nicely quantifies the basic assumptions given. Also, the model, its shortcomings and how they might affect the outcome are discussed well. I particularly like the analysis done for Fig 5. Overall, I don't see anything that needs major revising.

There are a few minor gripes, mainly with the form, though. On p1904,l1 a map with potential vegetation is mentioned, but I cannot find it.

Sorry, this figure can be found in supplementary information.

Also I think a native speaker should double-check the manuscript. The use of articles and prepositions is somewhat lacking, examples I found at first sight are p1904,l13 -> "the deforestation", p1905,l21 - >"of more than", p1906,l8 ->"In the tropical", p1907l19 "to the global", p1909,l2 ->"by an increase", p1910,l9 ->"which the relative", p1910,l24 ->"is a tendency" p1914,l7 ->"The albedo effect", p1969,l1 ->"of the climate", p1916l2 ->"on the surface", p1916,l4 ->"of the complex" or ->"of a complex".

Furthermore, I suppose on p1908,l16 you meant "change show linearity", and I'd drop the p1910,l14 "On the contrary" -> "whereas", or such, since there is no contardiction. Disclaimer: I am not a native English speaker.

Thanks for pointing out those language issues. We have carefully edited the manuscript by our native speaker co-authors and also the editing colleagues.

Abstract:

Previous modeling and empirical studies have shown that the biophysical impact of deforestation is to warm the tropics and cool the extra-tropics. In this study, we use an earth system model of intermediate complexity to investigate how deforestation at various spatial scales affects ground temperature, with an emphasis on the latitudinal temperature response and its underlying mechanisms. Results show that the latitudinal pattern of temperature response depends non-linearly on the spatial extent of deforestation and the fraction of vegetation change. Compared with regional deforestation, temperature change in global deforestation is greatly amplified in temperate and boreal regions, but is dampened in tropical regions. Incremental forest removal leads to increasingly larger cooling in temperate and boreal regions, while the temperature increase saturates in tropical regions. The latitudinal and spatial patterns of the temperature response are driven by two processes with competing temperature effects: decrease in absorbed shortwave radiation due to increased albedo and decrease in evapotranspiration. These changes in the surface energy balance reflect the importance of the background climate on modifying the deforestation impact. Shortwave radiation and precipitation have an intrinsic geographical distribution that constrains the effects of biophysical changes and therefore leads to temperature changes that are spatially varying. For example, wet (dry) climate favors larger (smaller) evapotranspiration change, thus warming (cooling) is more likely to occur. Our analysis reveals that the latitudinal temperature change largely results from the climate conditions in which deforestation occurs, and is less influenced by the magnitude of individual biophysical changes such as albedo, roughness, and evapotranspiration efficiency.

1. Introduction

Forests play a critical role in regulating climate through both biogeochemical and biophysical processes. Deforestation, driven by anthropogenic activities either directly, e.g., agriculture expansion, or indirectly, e.g., climate change induced disturbance (Allen *et al.*, 2010), can result in changes in earth's radiation balance, hydrological cycle, and atmospheric composition (Bonan, 2008). Deforestation is a major land conversion that has taken place historically over large scales and continues to be prevalent in the 21th century (Hansen *et al.*, 2013).

Previous climate model studies highlight the interesting observation that temperature response to deforestation appears to depend on latitude (Davin & de Noblet-Ducoudré, 2010). For example, large-scale deforestation in the tropics leads to temperature increase (Nobre *et al.*, 1991; Snyder *et al.*, 2004; Davin & de Noblet-Ducoudré, 2010) mostly due to the strong warming effect associated with reduced evapotranspiration. However, forest removal in the temperate and high-latitude regions results in surface temperature decrease. This decrease is explained by the dominant mechanism, albedo, which increases in the cleared land and leads to lower shortwave radiation absorption (Bounoua *et al.*, 2002; Snyder *et al.*, 2004). This albedo-induced cooling effect is particularly strong in the boreal regions where the snow mask effect is involved (Bonan *et al.*, 1992, 1995). In agreement with the climate model experiments, empirical studies using in-situ air temperature (Lee *et al.*, 2011; Zhang *et al.*, 2014) and satellite-derived land surface temperature (Li *et al.*, 2015) also show that the temperature effects of forests have a clear latitudinal pattern.

Moved down [1]: Compared with biogeochemical effects, i.e., release of CO_2 to the atmosphere that warms the global climate, biophysical effects are more heterogeneous,

Yan Li 1/28/2016 4:59 PM

Deleted: strongly felt at regional and local levels (Pitman *et al.*, 2012), and vary with season and location (Snyder *et al.*, 2004; Betts *et al.*, 2007, Li et al., 2015).

Compared with biogeochemical effects, i.e., release of CO_2 to the atmosphere that warms the global climate, biophysical effects are more heterogeneous, most strongly felt at regional and local levels (Bala *et al.*, 2007; Pitman *et al.*, 2012), and vary with season and location (Snyder *et al.*, 2004; Betts *et al.*, 2007, Li et al., 2015). It is thought that biophysical effect, especially albedo and evapotranspiration, are major biophysical mechanisms through which deforestation affects temperature in latitudinal patterns (Gibbard *et al.*, 2005). However, due to the high spatial variability of biophysical properties, the dominant mechanism and the net effect of deforestation could vary by particular location. This is further complicated by the influence of specific location's background climate on the altered water and energy balance. For example, previous studies show that climate conditions, such as snow and rainfall, can enhance or dampen biophysical effects (Pitman *et al.*, 2011; Li *et al.*, 2015). Such complexity is reflected in temperate forests, where the two biophysical mechanisms with opposite effects cancel each other, making their net effect much more uncertain compared to other forests. This incomplete understanding of temperate forests was confirmed by the mixed results obtained from modeling and observational studies (Bonan, 2008; Wickham *et al.*, 2013; Li *et al.*, 2015). Further complication comes from deforestation-triggered changes in other energy components (such as sensible heat) and multiple atmospheric feedbacks that can modify the albedo and evapotranspiration impact. Therefore, it is important to further investigate the relative strength of albedo and evapotranspiration impact on temperature change, and how much those factors are influenced by the interaction with the local climate and other factors.

Yan Li 1/28/2016 4:59 PM

Moved (insertion) [1]

Yan Li 1/28/2016 4:59 PM

Deleted: An interesting characteristic of deforestation is the observed latitude dependency in the temperature response, confirmed by previous climate model studies. Large-scale deforestation in the tropics leads to a temperature increase (Nobre *et al.*, 1991; Snyder *et al.*, 2004) mostly due to a strong warming effect associated with reduced evapotranspiration. However, forest removal in the temperate and high-latitude regions cools surface climate because the dominant mechanism is albedo increase that leads to lower shortwave radiation absorption in the cleared land (Bounoua *et al.*, 2002; Snyder *et al.*, 2004). This cooling effect is particularly strong in the boreal regions where the snow mask effect amplifies the albedo induced cooling (Bonan *et al.*, 1992, 1995). In agreement with the climate model experiments, empirical studies using in-situ air temperature (Lee *et al.*, 2011; Zhang *et al.*, 2014) and satellite-derived land surface temperature (Li *et al.*, 2015) also show that the temperature effects of forests have a clear latitudinal pattern. ... [1]

In addition to these biophysical effects, the spatial scale of deforestation is also an important factor in climatic impact. It has been shown that both spatial extent (global-regional-local) and degree of vegetation change (partial disturbance to complete removal) can alter the impact of deforestation (Sampaio *et al.*, 2007; Longobardi *et al.*, 2012). Evidence for this behavior is seen in the Amazon area, where depending on the spatial scale of deforestation, precipitation change can either exhibit a linear or non-linear relationship with vegetation change (Avissar *et al.*, 2002; Baidya Roy & Avissar, 2002; Souza & Oyama, 2010). And this relationship could even become opposite in sign (Runyan, 2012). The effect of vegetation change at various scales is still not clear on either the scale-dependency or latitudinal pattern of temperature response.

As described, the impact on temperature as a result of deforestation originates from the altered biophysical properties such as albedo, roughness, canopy conductance, surface emissivity, etc. The magnitude of some of these alterations, as well as their impact on temperature, may have inherent latitudinal patterns. For instance, the difference in albedo between forest and open land increases with latitude (Li *et al.*, 2015). By investigating how changes to several biophysical properties contribute to temperature change, we can better understand whether the latitudinal temperature response to deforestation is either directly due to these changes, or the processes that translate these changes to the surface climate response. Efforts have been made to quantify the contribution of each biophysical factor, including both empirical (Juang *et al.*, 2007) and modeling studies (Lean & Rowntree, 1997; Maynard & Royer, 2004; Davin & de Noblet-Ducoudré, 2010) that enable us to decompose the temperature change into components. Such studies can

Deleted: (Avissar *et al.*, 2002; Baidya Roy & Avissar, 2002; Souza & Oyama, 2010; Runyan, 2012). It is still not clear whether the temperature has such scale-dependent behavior, and whether the latitudinal pattern of temperature response would be modified.

Yan Li 1/28/2016 4:59 PM
Deleted: Deforestation impact originates from the altered biophysical properties such as albedo, roughness, canopy conductance, surface emissivity, etc., which cause temperature change via different paths. Some of these factors may have inherent latitudinal patterns. For instance, the albedo difference between forest and open land increases with latitude (Li *et al.*, 2015). The question now would be whether the latitudinal temperature response to deforestation can be attributed to biophysical changes, per se, or to the processes that translate perturbations to surface climate response, or to both. The answer to this question requires knowing how individual biophysical changes contribute to temperature change. Efforts have been made to quantify the contribution of each biophysical factor, including both empirical (Juang *et al.*, 2007) and modeling studies (Lean & Rowntree, 1997; Maynard & Royer, 2004; Davin & de Noblet-Ducoudre, 2010) that enable us to decompose the temperature change into components. Such studies can improve our knowledge of the mechanisms for the climate impact induced by vegetation change.

improve our knowledge on the mechanisms for the climate impact induced by vegetation change.

In this study, we use an earth system model of intermediate complexity (EMIC) to investigate how deforestation affects temperature through biophysical changes and also examine which physical mechanisms are responsible for the latitude-dependent temperature response (Section 2). To this aim, we first analyze latitudinal temperature changes in response to multiple deforestation scenarios by varying both spatial extent and deforestation fraction (Section 3.1 and 3.2). Next, we explore the possible causes for the latitudinal and spatial pattern of temperature change from both the surface energy balance (Section 3.3), as well as the background climate (Section 3.4). Finally, we show how different biophysical mechanisms affect temperature change and discuss their contributions to the latitudinal pattern (section 3.5). A brief discussion and summary are provided in Section 4.

2. Method

2.1 Model description

The UMD (University of Maryland) EMIC (Zeng, 2004) is used to perform the experiments. It consists of the global version of QTCM (Quasi-Equilibrium Tropical Circulation Model) atmosphere model (Neelin & Zeng, 2000), the physical land surface model Sland (Simple-land) (Zeng *et al.*, 2000), the dynamic vegetation and carbon model VEGAS (VEgetation-Global-Atmosphere-Soil) (Zeng, 2003; Zeng *et al.*, 2005), and a slab ocean model in which we use prescribed sea surface temperatures (SSTs) in our experiments.

Sland is a land surface model of intermediate complexity that is more complicated than the bucket model in its parameterization of evapotranspiration processes, aiming to model the first-order effects relevant to climate simulation. In this model, vegetation parameters such as leaf area index, roughness, stomatal conductance, and vegetation fraction depend on climate and are calculated by VEGAS. For surface albedo, seasonal climatology obtained from satellite is used as inputs (Darnell *et al.*, 1992). Vegetation-albedo feedback is treated in the model by introducing albedo anomalies. This procedure sums the albedo change due to vegetation change (calculated by VEGAS using an empirical formula as a function of leaf area index (LAI)), and the observed albedo climatology used by the atmospheric radiation module (Zeng & Yoon, 2009). This albedo anomalies treatment prioritizes the capture of the first-order effects of albedo change due to vegetation change, since many of the possible processes that are responsible for the observed albedo are difficult to model mechanistically.

It should be mentioned that Sland in its current setup does not explicitly account for surface snow, thus no snow-albedo feedback is included. This potentially leads to an underestimation of albedo change in regions with frequent snow. However, it also offers a unique opportunity to examine mechanisms other than snow in the temperature response to deforestation at high latitudes.

The VEGAS model simulates the dynamics of vegetation growth and competition among four plant functional types (PFTs): broadleaf tree, needleleaf tree, cold grass, and warm grass. The phenology of these plants is simulated dynamically as the balance between growth and respiration/turnover. The vegetation component is coupled to land and atmosphere through soil moisture dependence of photosynthesis and

2.2 Experiment design

UMD earth system model is a fully coupled model, but the setup for this study is an atmosphere-land-vegetation coupled version with prescribed ocean SST, and CO_2 concentration at the preindustrial level of 280 ppm, run at a resolution of 5.625° × 3.75°. The model is driven by a climatological seasonal cycle of SST derived from HadSST (Rayner *et al.*, 2006), averaged over 1960–1990 to smooth the influence of inter-annual climate variability. The model is first run for 500 years to allow for spin-up time during which vegetation is dynamically computed and reaches an equilibrium state with climate. Figure S1 shows the potential vegetation map obtained by the end of model spin-up. The vegetation map generally has a reasonable geographical distribution but does not perfectly match modern vegetation of the real world. This is expected because the potential vegetation is derived from an equilibrium state with climate. Therefore, any differences in the simulated climate compared to modern climate or any simulation bias, for example, in precipitation (Figure S2), could influence the vegetation distribution. In addition, some bias in simulated climate is expected for a model with intermediate complexity. Such bias is tolerable in our experiments due to the focus on the climate response to vegetation change and its mechanisms as opposed to an accurate reproduction

Yan Li 1/28/2016 4:59 PM
Deleted: ppv. The model is driven by a climatological seasonal cycle of SST, averaged for 1960-1990 to smooth the influence of inter-annual climate variability. The model is first run for 500 years to allow for spin-up time during which vegetation is dynamically computed and reaches an equilibrium state with climate. Figure S*1* shows the potential vegetation map obtained by the end of model spin-up. The vegetation map generally has a reasonable geographical distribution but is not perfect, for example, vegetation in Sahara region. This is because vegetation is mainly determined by simulated climate in the model, thus any simulation bias in precipitation (Figure S*2*) could influence the vegetation pattern more or less. For our analysis, the climatology over the last 10 years of spin-up is used as the control experiment (CTL). This is adequate for our simulation because of the small inter-annual variability in the model. Deforestation is imposed by setting the forest fraction in a given grid cell to zero (or a reduction with a given rate applied to the potential vegetation map), meaning forest is replaced by bare soil, as is also done in several previous studies (Bonan *et al.*, 1992; Bounoua *et al.*, 2002; Snyder, 2010). The sharp contrast between forest and bare ground is indicative of the maximum impact of deforestation.

of historical climate change. For our analysis, the climatology over the last 10 years of spin-up is used as the control experiment (CTL). This is adequate for our simulation because of the small inter-annual variability in the model.

Deforestation is imposed by setting the forest fraction in a given grid cell to the experimental value of either zero or a percentage of its original vegetation. This replaces the forest with bare soil, as is seen in several previous studies (Bonan *et al.*, 1992; Gibbard *et al.*, 2005; Snyder, 2010). An alternative strategy of implementing deforestation experiment is to replace trees with grass (crop). This is considered to be more “realistic” than replacing trees with bare ground (Davin & de Noblet-Ducoudré, 2010). The conversion of trees to grass is expected to induce a similar but less pronounced impact on climate (Gibbard *et al.*, 2005), compared to the conversion of trees to bare ground which would represent the maximum impact of deforestation. Despite this difference, both strategies are frequently used in existing literature to represent deforestation, and they yield consistent findings as the operating mechanisms and feedbacks are the same. In the simulation for deforestation experiment, modified vegetation fractions are fixed so that the vegetation model becomes “static” rather than “dynamic”.

Formatted Table

Three groups of experiments are designed to study different aspects of the deforestation impact (Table 1): (I) deforestation with different spatial extents (II) with different deforestation fractions; (III) with individual biophysical factors changed separately. The first two groups address the spatial scale problem for the climatic response to deforestation. Group (I) consists of three regional deforestation scenarios that take place in the tropical (20°S-20°N), northern temperate (20°N-50°N) and boreal (50°N-90°N) regions, and one global deforestation scenario in which all forests are cleared. Group (II) consists of four global deforestation experiments in which forest fractions are reduced as a percent to its original coverage at 25% to 100%. The 100% clearing creates the same experiment as the global deforestation in group I, labeled ALL

Group (III) is designed to separate the effect of individual biophysical factors by which deforestation affects climate. Inspired by Davin & de Noblet-Ducoudre (2010), three experiments are devised to quantify the impact from changes in albedo, roughness, and evapotranspiration efficiency. Our experiment for albedo and roughness differs from Davin & de Noblet-Ducoudre (2010), who compared the case with only “one factor changed” with the case of “everything unchanged”. In contrast, we ultimately compare the case of “everything changed with one factor unchanged” with the case of “everything changed”. Our experiments include global deforestation with albedo unchanged in “noALB”, roughness unchanged in “noRGH”, and evapotranspiration efficiency effect isolated in “EVA”. In noALB experiment, albedo change induced by forest removal is not passed to the atmosphere, which means “no albedo change” indeed in the atmosphere model since it intakes observed albedo data. The other biophysical variables are still being affected by deforestation. Thus, the albedo effect can be isolated by calculating the

difference (ALL – noALB) between the regular global deforestation simulation (ALL) that includes the albedo change and the noALB experiment. In noRGH experiment, roughness is set to be unaffected by forest clearing, therefore, the difference ALL - noRGH can be attributed to the roughness effect. The calculation of evapotranspiration involves many parameters. For example, both albedo and roughness can affect ET. Therefore, for EVA experiment, a different strategy is adopted by fixing both albedo and roughness (as in CTL) while other variables are allowed to change. Thus, the difference of EVA and control, EVA - CTL, reflects processes other than albedo and roughness that can affect ET, representing the pure hydrological effect of deforestation that refers to the ability of vegetation to transfer water from the soil to the atmosphere (Davin & de Noblet-Ducoudré, 2010).

All deforestation simulations are initialized with the restart files after spin-up whose vegetation map, relevant parameters, and model codes have been modified as described above. Each simulation is run for 100 years and the averaged results of the final 10 years are used for the analysis. Ground temperature is used to analyze temperature change, because the model does not output the 2-m air temperature. Ground temperature has a strong signal of the locally induced temperature change, which is closely coupled to the surface energy balance. This enables us to focus on the local and regional impacts of vegetation change. Only model grid points with forest fractional change larger than 0.1 are analyzed for robustness. The resulting changes in LAI, albedo, and roughness, induced by global deforestation, are provided in Supplementary Information (Figure S3–S5).

3. Results

3.1 Latitudinal temperature change in response to deforestation

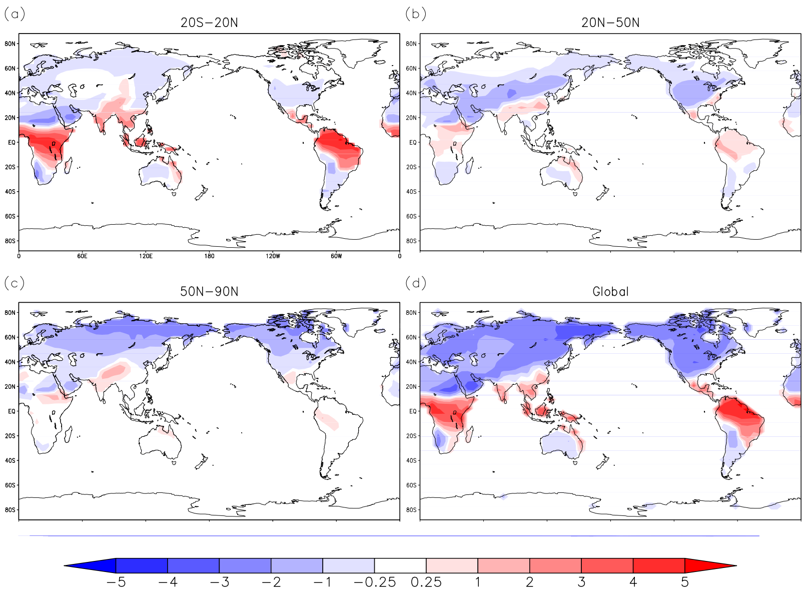

Figure 1. Ground temperature change for (a) tropical (20°S-20°N), (b) northern temperate (20°N-50°N), (c) boreal (50°N-90°N), and (d) global (90°S-90°N) deforestation (Unit: K)

The latitude-dependence of temperature response is confirmed by the three regional deforestation experiments (see Figure 1a-c for tropical, northern temperate and boreal, and Figure 1d for global deforestation experiments). The deforestation impact in the simulation is a very strong signal relative to the small inter-annual variability, making almost all changes over the land statistically significant. Therefore, significance levels are not shown on the map. In tropical deforestation (20°S-20°N) experiment, a significant

and widespread warming is observed over deforested regions by 2.22 K (Table 2), greatest (~4 K) in the Amazon and Central Africa regions and about 1-2 K in South Asia and the east coast of Australia. Although warming is the dominant effect, there are areas around Sahel, North Africa in which we observe cooling up to -2 K. This suggests temperature response can differ within a latitude band, as shown in earlier studies (McGuffie *et al.*, 1995; Snyder *et al.*, 2004). The regional difference is partly due to the regional circulation patterns being affected differently by deforestation (McGuffie *et al.*, 1995). Temperature outside the deforestation boundary (e.g., South Asia, North Canada) is also influenced by the tropical deforestation, indicating that the vegetation disturbance signal can spread to distant regions through atmospheric processes. Replacing forest with bare ground leads to a surface albedo increase of 0.26, and a decrease of shortwave absorption at the surface by 38 W/m^2. Precipitation and evapotranspiration also decline drastically by 3.75 and 2.93 mm/day, respectively, while sensible heat increases. Reducing cloud cover results in an increase in downward shortwave and a decrease in downward longwave radiation (Table 2).

In the northern temperate region (20°N-50°N), deforestation causes a temperature decrease of -0.84 K over most areas. North China and most parts of the United States show the largest cooling (~-1.5 K) while a weaker cooling (< -1 K) is observed in Europe. Nevertheless, temperature rise can be found in some areas like South China (1~2K) and Southeast U.S. (~1 K), similar to the tropics. The regional difference also reflects the different response of the surface energy balance to deforestation, and is related to the background climate as discussed in the next section. Other changes, including increased albedo and decreased shortwave absorption as well as decrease in ET and precipitation,

can be seen in temperate deforestation, but the magnitudes are much smaller than those in the tropics. Unlike the tropical region, sensible heat decreases in the temperate region and is consistent with the sign of temperature change.

Compared with the temperate region, deforestation in the boreal region results in a stronger cooling of -1.70 K but changes in the surface energy components are much smaller. It should be noted that albedo only increases by 0.22 because of no snow-masking effect in the land surface model, which could enhance the cooling signal by amplifying the albedo change. Nevertheless, a considerable cooling is seen in our results without the snow-masking effect, suggesting that other changes rather than snow contribute to the cooling effect of deforestation.

Table 2. Changes in key climate variables from regional and global deforestation experiments. "Δ" denotes change relative to the control experiment. The value for each climate variable is the area-weighted change over deforested areas for different latitude zones. The symbol "↑" denotes upward and "↓" denotes downward. Units are W/m^2 for energy flux, K for temperature, mm/day for precipitation, and unitless for albedo.

3.2 Sensitivity of temperature change to spatial extent and degree of vegetation change

The influence of spatial extent of deforestation can be clearly seen by comparing the temperature response in a given region under regional and global deforestation experiments. While similar in spatial pattern, temperature change in the global deforestation experiment (Figure 1d) is much stronger than those in the regional deforestation, especially in mid and high latitudes (Table 2). From the regional to global scale, deforestation-induced cooling increases from -0.84K to -1.56K, and from -1.70K to -2.42 K in the northern temperate and boreal regions, respectively. In contrast, warming in the tropics is less affected and even slightly decreases from 2.22K in the regional deforestation case to 2.06K in the global case. This is because global deforestation leads to a stronger reduction of both absorbed shortwave radiation and downward longwave radiation, both amplifying the cooling effects (Table 2) that reduce tropical warming and enhance high-latitude cooling. Such dampened tropical warming and enhanced extra-tropical cooling from regional to global deforestation experiments are supported by a recent study (Devaraju *et al.*, 2015). Overall, an amplified temperature change in the global deforestation experiment is expected as it generates a stronger perturbation in the

atmosphere, but the latitudinal temperature response is well preserved despite the increase in the spatial extent of deforestation from regional to global.

By looking at a set of experiments with varying deforestation fractions, we found temperature change is also sensitive to degree of vegetation change (see Figure 2, Table 3). Deforestation fraction refers to the percentage of trees removed relative to the original coverage (25%, 50%, 75%, and 100%), which is representative of the real areas that have been deforested. For 25% deforestation fraction, temperature is virtually unaffected in most areas except for a weak warming in the tropics. As forest-loss fraction goes up to 50%, a latitudinal temperature change emerges with discernible tropical warming and weak cooling in mid and high latitudes (Figure 3). Higher deforestation fractions of 75% and 100% result in a greater temperature change and a more prominent latitudinal pattern. Generally, the magnitude of temperature change responds nonlinearly to increases of deforestation fraction, with much larger changes at high deforestation fractions (Figure 3, Table 3). This nonlinearity can either arise from the response of biophysical land parameters to deforestation, or from the climate response (i.e., temperature response) to biophysical changes. We found nonlinearities in both of these aspects (Figure S6).

3.3 Role of surface energy balance in latitudinal temperature change

Temperature change is driven by altered surface energy balance in response to forest removal. Among them, changes in shortwave radiation absorption (ΔSW) and evapotranspiration (ΔET) can largely determine the sign and magnitude of temperature response to deforestation. Deforestation can increase surface albedo, leading to reduced absorbed shortwave radiation at the surface (ΔSW) which acts as a cooling mechanism, while decreased ET (ΔET) can produce a warming effect due to weakened latent cooling.

Figure 4c shows the latitudinal pattern of ΔSW and ΔET. Although the largest decreases are observed in the low latitudes and become smaller as latitude increases, the relative importance of these two varies across latitudes as also reported in Davin & de Noblet-Ducoudre (2010) and Li *et al.* (2015). In the tropics, ET declines (warming effect) more than the absorbed shortwave radiation (cooling effect). This ΔET-dominated energy imbalance is compensated by increase in temperature, outgoing longwave radiation, and sensible heat. Beyond the tropics, the opposite occurs, as ET declines less than absorbed shortwave radiation, therefore temperature and sensible heat decrease in response to the ΔSW dominated energy imbalance. Specifically, mid latitude is a transition region where ΔET and ΔSW in the south are relatively close to each other but in the north are quite different. In high latitudes, ΔET is negligible whereas ΔSW maintains similar magnitude as in the mid latitudes, thus resulting in the most significant temperature decrease.

Although ΔSW and ΔET determine the basic latitudinal pattern of temperature change, changes in downward longwave radiation (ΔLW↓) and sensible heat (ΔH) also have

influence. While ΔSW↓ (changes in downward shortwave) could be considered as a part of atmospheric feedback due to cloud cover change, we find that ΔSW is still dominated by ΔSW↑ (changes in upward shortwave) due to albedo change (Figure S7). ΔLW↓ decreases across all latitudes due to less cloud cover, while sensible heat increases in the tropics and decreases in other latitudes. ΔLW↓ is combined with ΔSW to give the available energy (ΔAva=ΔSW+ΔLW↓) and ΔH is combined with ΔET to give the turbulence energy (ΔTub=ΔET+ΔH), corresponding to the changes in received and dissipated energy, respectively. Available energy warms the land surface while turbulence energy cools the surface (de Noblet-Ducoudré *et al.*, 2012). The difference of these two is the outgoing longwave radiation, which is a function of ground temperature, and is equivalent to ground temperature change. As shown in Figure 4d, the latitudinal changes of the available and turbulence energy largely resemble that of ΔSW and ΔET, but with some noticeable differences. Comparing with ΔSW, reduction in available energy (ΔAva) is larger across all latitudes, suggesting an amplifying feedback mechanism through ΔLW↓ due to reduced cloud cover (more reduction in ΔSW+ΔLW↓, Figure 4a). However, ΔTub is smaller than ΔET in the tropics (less reduction for ΔET+ΔH, Figure 4b) but larger than ΔET in the mid and high latitudes (more reduction for ΔET+ΔH, Figure 4b), showing that the warming signal can be either weakened or enhanced when ΔH is considered (see Table 2). Overall, the latitude pattern of ΔSW and ΔET in the southern hemisphere is influenced more by ΔLW↓ and ΔH than in the northern hemisphere. In the southern hemisphere, the originally large energy difference between ΔSW and ΔET disappears when ΔLW↓ and ΔH are accounted for, resulting in a dampened energy difference of ΔAve and ΔTub.

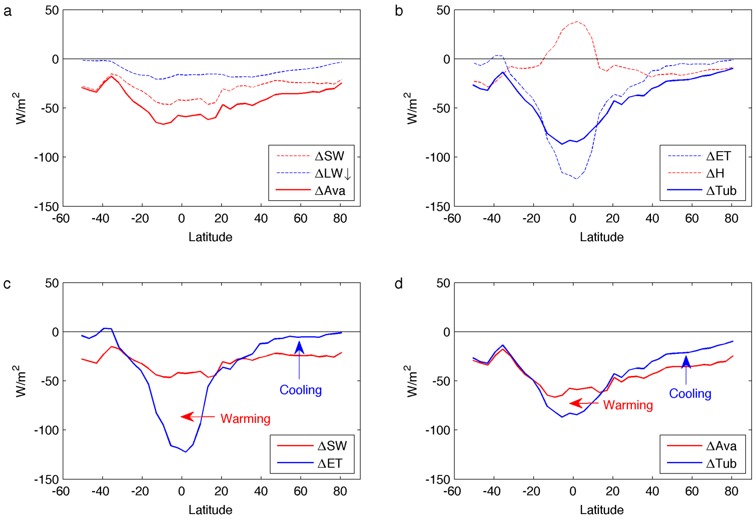

Figure 4. Latitudinal pattern of changes in surface energy balance. (a) Changes in absorbed shortwave radiation (ΔSW), downward longwave radiation (ΔLW↓), and available energy (ΔAva=ΔSW+ΔLW↓). (b) Changes in evapotranspiration (ΔET), sensible heat (ΔH), and turbulence energy (ΔTub=ΔET+ΔH). (c) ΔSW and ΔET. (d) ΔAva and ΔTub

Analysis above shows that the basic latitudinal pattern of ΔSW and ΔET can explain most of the latitudinal temperature response regardless of other changes and feedbacks (e.g., changes in downward longwave radiation and sensible heat). Here we evaluate the extent to which relative importance of ΔSW and ΔET can explain the spatially varying temperature change in terms of its sign and amplitude. The sign of temperature change can be approximated by a simple ratio of ΔET/ΔSW. The accuracy of this approximation depends on the strength of the basic pattern imposed by ΔSW and ΔET against other

changes. A larger-than-one ratio suggests ΔET warming exceeds ΔSW cooling and temperature is likely to increase, whereas a smaller-than-one ratio suggests ΔSW cooling is stronger than ΔET warming and temperature tends to decrease. We used results from the regional deforestation numerical experiments to demonstrate this feature. Figure 5 shows the deforested grid points in the model with their ΔET and ΔSW plotted on the x and y axes, with colors representing the sign of temperature change. Deforested points with increased temperature (red) are often located in the upper-left space of the ΔET = ΔSW line where warming is anticipated (ΔET >ΔSW), while points with decreased temperature fall into the lower-right space where cooling is anticipated (ΔET < ΔSW). It turns out that ΔET and ΔSW alone can explain 93%, 88%, and 99% of deforested points for the direction of temperature change in the tropical, temperate, and boreal regions, respectively. In addition, there is tendency towards smaller ΔET/ΔSW ratios at higher latitudes and drier areas in the global deforestation experiment (Figure S8), suggesting a decreasing importance of ΔET over ΔSW. Few exceptions exist because longwave and sensible heat changes may also influence temperature change but are not considered here. Furthermore, the amplitude of temperature change is related to the difference of ΔSW and ΔET. As shown in Figure 5d-f, ΔSW - ΔET is highly correlated with the amplitude of temperature change in the tropical (r=0.96) and temperate regions (r=0.79), but not in the boreal region (r=0.27).

3.4 Influence of background climate on surface energy change and temperature change

The latitude-dependent pattern for ΔSW and ΔET could arise from the intrinsic latitudinal distribution in background climate, e.g., solar radiation and precipitation/ET decrease with latitude increase. Therefore, the same amount of albedo change would translate into a larger ΔSW in lower latitudes due to the geographic distribution of solar radiation. Likewise, given the same ET reduction rate, a larger ΔET is expected in the tropics than in high latitudes.

The influence of background climate can be illustrated by a simple calculation. Assume that deforestation causes albedo increase by 0.02, 0.05, 0.12, and 0.23 uniformly across all latitudes and ET decrease by 15%, 30%, 50%, and 75% compared to their baseline climatology, respectively. Multiplying these change rates by the baseline shortwave radiation and ET, we obtain the corresponding ΔSW and ΔET without considering any climate feedback. For demonstration purpose, the change rates chosen here for albedo and ET roughly correspond to the global averaged changes in the four deforestation fraction experiments (deforestation fraction ranges from 25% to 100%, see group II experiment). Interestingly, the calculated ΔSW and ΔET (Figure 6) agree well with the simulation (Figure 4c). The main features, including ΔET > ΔSW in the tropics and ΔET < ΔSW in the extratropics, are captured. We also used the satellite derived ET and shortwave radiation data from Li *et al.* (2015) to perform the calculation (see Figure

S9). The results generally support the findings from Figure 6, except for the two combinations with small changes in albedo and ET. For these two cases, the anticipated pattern is not captured mainly because of the chosen low albedo change in high latitude, which leads to an underestimation of ΔSW. It should be emphasized that the albedo and ET change rates in reality have more complicated patterns than what we assume in the calculation. Nevertheless, our simple calculation still reveals the role of the baseline climate in shaping the latitude-dependent temperature change to deforestation.

Further evidence comes from the spatial relationship between background climate and temperature response to deforestation. We found baseline precipitation is highly correlated with ΔET (r=-0.98) and with ΔT (r=0.87), suggesting that precipitation can influence temperature change by controlling ET change. This is also supported by the ratio of ΔET/ΔSW in Figure S8 where larger ΔET over ΔSW is found in wetter areas, and by observations from air temperature (Zhang *et al.*, 2014) and physical mechanisms pertaining to soil moisture (Swann *et al.*, 2012). Therefore, spatial variation of temperature change is partly due to background climate. For instance, temperature decreases in the tropical deforested areas like Sahel, west Amazon, and southwestern Africa, because dry climate limits ΔET, thus temperature change is dominated by the cooling effect from ΔSW. In contrast, in wet temperate deforested areas like South China, India, and parts of North America, temperature increases because of the dominant warming effect from ΔET.

3.5 Contribution of individual biophysical processes to the latitudinal temperature change

The aforementioned changes in temperature and surface energy balance are triggered by the altered biophysical variables such as albedo, roughness, ET efficiency, etc. as a result of deforestation. The effect of each individual biophysical factor and its contribution to temperature change are evaluated in this section.

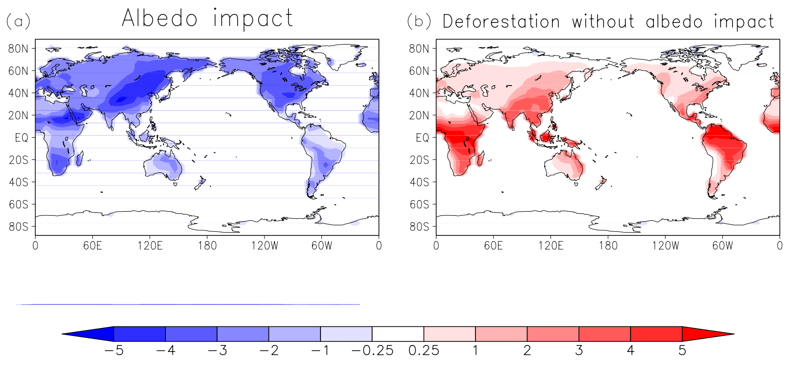
(1) Albedo

The impact of albedo change can be isolated by the difference of ALL – noALB (see Method Section), as shown in Figure 7a. As expected, albedo change causes significant temperature decrease over all affected regions. Surprisingly, the strongest cooling appears in the northern temperate region instead of the tropics where the largest albedo increase occurs (Table 4). This indicates the strength of perturbation is not the only factor for determining spatially varying temperature change. The magnitude of cooling in the boreal region is similar to the temperate region, because of no amplified albedo change due to snow. If deforestation did not change albedo, there would be a substantial warming over all affected regions (noALB – CTL, Figure 7b), accompanied with decreased ET and very little change in absorbed shortwave radiation (SW). This is expected because the warming effect of ΔET dominates temperature change when albedo effect is absent.



(a) Albedo impact

(b) Deforestation without albedo impact

Roughness can affect turbulence (ET as well as sensible heat) flux between land surface and atmosphere. Higher roughness facilitates absorbed shortwave energy to be dissipated as turbulence, while smaller roughness suppresses this process and could have a warming effect. Effect of roughness on climate can be isolated by the difference All – noRGH. Roughness change as well as its impact are more pronounced in the tropical region (Table 4). As is seen in Figure 8a, reduced roughness warms most areas except for the upper northern latitudes, with warming decreasing from the tropics to high latitudes; see also Davin & de Noblet-Ducoudre (2010). Without roughness change, deforestation would cause less warming (Figure 8b) and less reduction in turbulence energy (not shown) than regular deforestation. Moreover, Figure 8b also shows the combined effects from albedo and evapotranspiration efficiency since roughness effect is excluded. Thus, the existence of a tropical warming in some regions implies that the reduction in evapotranspiration efficiency remains dominant and outweighs the albedo impact in this situation.

(3) Evapotranspiration efficiency

Evapotranspiration efficiency refers to the ability of partitioning available energy into evapotranspiration more than into sensible heat. The conversion of forest to bare land favors more turbulence energy to be transferred in the form of sensible heat rather than ET, resulting in higher Bowen ratio. The impact of altered ET efficiency can be separated by EVA – CTL, showing a noticeable warming in the tropical regions and some parts of the temperate region, and negligible impact in high latitude (Figure 9). It seems that changed ET efficiency has a significant impact only over regions with wet climate, which may be due to the close coupling between precipitation and ET change.

Table 4. Summary of influence of individual biophysical factors on temperature change. Numbers in parentheses are changes in albedo and roughness. Albedo is unitless and unit for roughness is m.

	Global (ALL – CTL)	Albedo (ALL – noALB)	Roughness (ALL-noRGH)	Evapotranspiration efficiency (EVA – CTL)
50°N-90°N	-2.42	-2.93 (0.22)	0.05 (0.86)	0
20°N-50°N	-1.56	-3.1 (0.18)	0.86 (0.66)	0.27
20°S-20°N	2.06	-1.92 (0.28)	1.92 (1.33)	1.22

ALL: global deforestation; noALB: global deforestation without albedo change; noRGH: global deforestation without roughness change; EVA: global deforestation without both albedo and roughness change.

By summing up the contributions from individual biophysical factors linearly (ALL – noALB + ALL – noRGH + EVA – CTL), we reconstruct temperature change, which closely agrees with the actual signal (ALL – CTL) in terms of both latitudinal (Figure 10) and geographical patterns (Figure 11). Latitudinal features are inherited in the contribution of each individual component (Table 4). Albedo effect generally increases with latitude whereas roughness and evapotranspiration efficiency effects decrease with latitude. Therefore, the largest temperature increase in the tropical region (2.06K) originates from the warming effect of changed roughness (1.92K) and evapotranspiration efficiency (1.22K), and is counteracted by a comparatively small albedo cooling (-1.92K). In the extratropics, temperature response is dominated by albedo cooling, with similar strengths in the northern temperate (-3.01K) and boreal (-2.93K) regions. But such cooling is partially canceled by the weaker warming effect of roughness (0.86K) and evapotranspiration efficiency (0.27K) in the temperate region and no compensation at all

in the boreal region. The latitudinal pattern caused by each biophysical factor is less likely to be due to the latitudinal signal from biophysical change per se, because biophysical change does not match the latitude pattern of temperature response. For example, the largest temperature change does not occur where the largest biophysical change (e.g., albedo and roughness) occurs. This shows the complex interactions in the translation from the initial perturbation to subsequent climate response, which varies by latitude. Biophysical impacts are strongly regulated by the baseline climate where vegetation change occurs, as also demonstrated in Pitman *et al.* (2011).

4. Discussion

Our results show patterns of temperature change as a result of deforestation that are in line with the conclusions of previous modeling studies, e.g., strong tropical warming (Nobre *et al.*, 1991; Snyder *et al.*, 2004), moderate temperate cooling, and strong boreal cooling (Bonan *et al.*, 1992, 1995; Betts, 2000), but few of them consider the spatial scale of deforestation. We found that temperature change varies nonlinearly with both the spatial scale and the fraction of forest removed, with increasingly larger temperature change as disturbance grows, but the overall latitudinal pattern is not altered. This scale-dependent relationship between temperature change and deforestation reflects a perturbation-response relationship derived from the existing mechanisms of the model in which non-linearity is found. However, it does not exactly emulate the influence of physical processes operating at various scales in the real world, because many scale-related processes cannot be fully resolved in a model with a fixed complexity. For

Deleted: The patterns, shown in our results, of temperature change as a result of deforestation are in line with the conclusions of the previous modeling studies, e.g., strong tropical warming (Nobre *et al.*, 1991; Snyder *et al.*, 2004), moderate temperate cooling, and strong boreal cooling (Bonan *et al.*, 1992, 1995; Betts, 2000), but very few of them considers the spatial scale of deforestation. We found that temperature change varies nonlinearly with both the spatial scale and the fraction of forest removed, with increasingly larger temperature change as disturbance grows and little change in the latitudinal pattern. This scale-dependent feature in temperature change reflects a perturbation-response relationship derived from the existing mechanisms of the model, but it does not exactly emulate the influence of physical processes operating at various scales in the real world, because many scale-related processes cannot be fully resolved in a model with a given complexity. For example, many meso-scale processes cannot be included in a global model. This makes it difficult to compare our results to those from observational studies that span different spatial scales.

... [20]

example, many meso-scale processes cannot be included in a global model. This makes it difficult to compare our results to observational study results that span different spatial scales.

We found that changes in shortwave radiation absorption (ΔSW) and evapotranspiration (ΔET) can largely determine the sign and amplitude of temperature change, as well as its latitudinal and spatial patterns in response to deforestation. In a global deforestation scenario, more than 90% of the sign of temperature change over deforested areas can be explained by ΔSW and ΔET. Although ΔET and ΔSW can be influenced by other factors and feedbacks, they still provide useful diagnostic information for temperature change and serve as a first order approximation. Using this information, albedo and ET changes (two variables readily available from satellite data) can be potentially applied to evaluate the possible impact of undergoing land cover change on local and regional temperature (Loarie *et al.*, 2011; Peng *et al.*, 2014; Li *et al.*, 2015).

To a large extent, the latitude-dependent temperature response to deforestation and its spatial variability can be attributed to background climate condition, such as solar radiation, precipitation, and snow, which in turn affect the biophysical impact of vegetation change. Further evidence comes from the contribution of each biophysical factor, i.e., albedo, roughness, and ET efficiency, on the temperature response. Although these factors drive temperature change in different directions, their contributions also have clear latitudinal patterns (Davin & de Noblet-Ducoudre, 2010). This indicates that climate condition manifests its influence either explicitly in the temperature response through controlling changes on surface energy balance, or implicitly in the magnitude of biophysical alteration triggered by deforestation. After careful analysis of our model, our

results show that the latitudinal pattern of temperature change is due to the explicit impact of climate condition.

We acknowledge certain limitations and important issues that are not fully addressed in this study. Previous studies showed an important role of oceanic feedback which could cause additional cooling through albedo change (e.g., sea-ice albedo feedback) and could override temperature change over land in mid latitudes (Claussen *et al.*, 2001; Davin & de Noblet-Ducoudré, 2010), but our ocean model is not interactive so such dynamics could not be studied here. In the simulation, we used the SST climatology of 1960-1990 with seasonal cycle only that can minimize inter-annual variability and therefore amplify the strength of deforestation signal to climate variability in terms of statistical significance. If a different period of the SST climatology had been used, the simulated climate may have been slightly different including differences in vegetation distribution and deforestation impacts. Nevertheless, our results are unlikely to be substantially changed by the choice of SST climatology, because a background climate change as large as that coming from 1× CO$_2$ (280 ppm) increased to 2×CO$_2$ (280 ppm) can only modify the climate impact over certain transitional regions (Pitman *et al.*, 2011).

Furthermore, in this study we use ground temperature as the variable for accessing the deforestation impact. In other studies, and perhaps more commonly, this component could be analyzed using air temperature, although research based on ground temperature (McGuffie *et al.*, 1995; Kendra Gotangco Castillo & Gurney, 2012) or surface temperature (Davin & de Noblet-Ducoudré, 2010) is also seen in the literature. Although these two have been shown to often agree with one another at larger scales (Jin *et al.*, 1997), it is worth investigating whether they have different responses to vegetation

Finally, results from a single model are subject to uncertainty and some features might be model-dependent. For instance, some biases in the simulated climate of the model may lead to shifts in vegetation distribution and thus could influence the deforestation impact. To combat this, model inter-comparison projects like Land-Use and Climate, Identification of Robust Impacts (LUCID) experiments (Pitman *et al.*, 2009) can help to distinguish robust findings against model uncertainty. The participant models in LUCID show consistency in how land cover change affects available energy but diverge greatly on energy partition between latent and sensible heat flux changes (de Noblet-Ducoudré *et al.*, 2012), indicating large uncertainty lies in the response of non-radiative process to land cover change, especially for ET (Boisier *et al.*, 2012). Therefore, considerable effort is required to improve model performance in the simulation of land processes, and new inter-comparison projects such as LUMIP (Land Use Model Intercomparison Project, https://cmip.ucar.edu/lumip) are highly valuable. In addition, observational studies are indispensable as they can offer new insights and serve as a reference benchmark for model results, especially those using new techniques and datasets such as satellite data.
