Dear Editor-in-chief,

Thank you for the consideration of our manuscript. This file includes our previous point-by-point response to the reviewers and the tracked changed version of our new manuscript. The track changes to the supplementary file are also included at the end.

On behalf of the authors,
Chris Colose

We appreciate the time and effort by the referee in reviewing this manuscript. We will address all issues, as highlighted below (reviewer text in red):

"The ITCZ shifts away from the hemisphere with greater forcing"- please specify that you mean greater NEGATIVE or VOLCANIC forcing.

Agreed that this is improved phrasing, we will correct to "The ITCZ shifts away from the hemisphere with greater volcanic forcing."

Line 136- how many latitudinal bands does G08 use? Also line 144- could you add some more detail about the G08 dataset and how it was derived- e.g. ice core based? And more information about the aerosol transport model?
and,
Line 157 The stratospheric sulfate aerosol loadings given by G08 are a function of latitude, altitude and month"- What resolution is G08 both horizontally and vertically?

The G08 dataset provides sulfate aerosol loading from 9 km to 30 km (at 0.5 km resolution) for each 10° latitude belt (from 90°S to 90°N − i.e., 18 latitude bands). It is indeed derived from ice core sulfate records. We will add more information in the revised manuscript.

Line 140- "the impact of these smaller amplitude and slowly varying forcings is very small."- Did you test this, or is it speculation?

During the preparation of this paper, this was tested in single-forcing runs in CESM, and also with multiple (simultaneous) forcings in the GISS model (each without volcanoes). The "composite" results obtained by averaging over the same dates as in the volcano composites are indistinguishable from noise, and averaging over hundreds of "events" would produce a nearly blank anomaly map (white almost everywhere), due to averaging out internal variability and the fact that any instance of solar or land-use forcing (relative to a five year interval immediately prior) will be extremely small. If the analysis were repeated in a control simulation, the results would be indistinguishable.

Line 154- is this at different levels in the stratosphere as well?

Yes− in the GISS model, there is an optical thickness from 15-35 km. We will make a note of this in the revised text.

Line 175- How big is Pinatubo for comparison?
Pinatubo remains elevated at ~20-30 Tg sulfate aerosol in the G08 dataset for about a year, and drops off to <1 Tg after 4-5 years. We will add this to the revised text.

Line 184- is there any reason for using MJJAS and NDJFM for the warm and cold season rather than MJJASO and NDJFMA? I expect the results would be similar, but I'm just intrigued!

In our analyses, we intended only to capture any sensitivity of the anomalous response to seasonality, and we feel our choice is appropriate for that target. In the early stages of the manuscript we did the analysis for DJF and JJA, and decided to expand the month range to include more of the data, but the conclusions did not change, and any differences were barely noticeable "by eye."

Lines 217-218 – "The G08 reconstructions used a simple transport model that does not allow for cross-equatorial aerosol transport" –I'm a bit confused as to what exactly this means and what the implications are- does it mean that if an eruption happens one side of the equator that none of the aerosols go to the other side?

We apologize for the confusion, and will modify the text. Two datasets emerged from the G08 study, the first an aerosol injection dataset for each hemisphere (in mass units). The second dataset (used for forcing GCMs) provides latitude/altitude information of aerosol concentration, at the resolutions previously mentioned. In the second dataset, the spatial evolution was derived from a simple model that parameterizes transport between the tropics, extratropics, and poles, and they interpolated the vertical distribution of aerosols based on information from the Pinatubo eruption. Cross-equatorial transport of aerosol was not allowed, and so tropical eruptions that left an imprint in both Polar Regions were represented by separate aerosol injections in both hemispheres. This was done since the ice core estimates provide information on the hemispheric distribution of volcanic aerosols, information that could only be preserved in their setup if hemisphere-only transport was permitted.

It is true that these details influence the volcanic forcing in all of the CMIP5/PMIP3 (and CESM LME) runs that utilized G08, and we do not take a position in this paper on the realism of the reconstruction. Improvements in volcanic forcing are at the forefront of research on last millennium climate, and we expect advances in CMIP6. For our purposes, however, this does not matter since the different composites ($ASYMM_{NH}$, $ASYMM_{SH}$, SYMM) have been formed from a forcing distribution that was imposed on the GCM and is perfectly defined. Thus, while forcing uncertainty (either in timing, magnitude, or spatial structure) is an important consideration for connecting the model results with paleoclimate proxy data, the responses we report are self-consistent with the forcing.

Line 221- does this imply that Tambora has more aerosols in the NH than SH? Or that it is symmetrical. Can you be more specific?

Tambora is actually a SYMM event in our composites (and would be if we used the Crowley volcanic reconstruction as well), based on the criteria we used of a <25% ratio in hemispheric-mean aerosol loading. However, there are slightly more aerosols in the NH in G08 and slightly more in the SH in Crowley. We will clarify this, but the main point in making this statement was that there is uncertainty in the reconstructions.

Line 248 “In the ASYMMNH and SYMM results, the cooling peaks over the Eurasian and North American continents.” - But not in SYMM MJJAS

This is correct, we will modify the text. Thank you.

Line 250: Mid latitudes? or is it more high latitudes? Maybe mid to high latitudes?

We will write “mid-to-high latitudes.” Thank you.

Line 264: “suggesting AET away from the forced hemisphere” Do you mean towards?

Yes, thank you for spotting this typo.

Line 271: “after normalizing each event by a common global aerosol mass excursion, thereby accounting for differences in the average forcing among the different eruptions”. Maybe add a caveat that this doesn’t take into account things like coagulation of aerosols for bigger eruptions which tends to reduce climate effects for a given mass of aerosols (see Timmreck et al 2009), and assumes that the response pattern scales linearly. For ITCZ excursions, the end of the paper suggests that this is not the case for asymmetric forcing- the ITCZ moves more for a bigger forcing gradient between hemispheres.

Agreed on all points, thank you. We will modify the text to caution interpreting a normalized metric in the presence of non-linear effects.

Line 288- does this alignment error affect all/many eruptions in this dataset? Or is it just Laki?

Most eruptions are not impacted. There were a few smaller events that were also not included or mis-aligned, described in http://climate.envsci.rutgers.edu/IVI2/IVI2Version2ReadMe.pdf (all of the participating models that used G08 used version one of this dataset). We will carefully check whether any of our dates require a similar caveat as we did for Laki, which is a much larger and more well-known NH (Icelandic) eruption.

Line 323- Maybe mention some more of the ENSO and volcano studies that have been done in the past- Whether or not volcanoes influence ENSO was certainly a bit of a controversial issue in the literature at one point. I am not totally up to date with the most recent studies though. Line 336- how big is a 0.5 C El Nino anomaly compared to a typical El Nino event in the model? (e.g. a 1 standard deviation event?) Also, is it statistically significant?

We will add citations to the revised manuscript to improve the ENSO segment.

In CESM, the El Niño events are too large (relative to observed amplitudes over the historical period) and a 0.5 °C anomaly is well within the model’s range of natural variability. However, the composite results always represent an average over hundreds of events, and the event mean stands out following volcanic eruptions (Figure S6). We will improve the statistical justification for this conclusion in the revised manuscript. We interpret the positive SST anomalies in the eastern Pacific (in the composite) as a forced response, or equivalently, we argue that volcanoes pre-condition the system toward El Niño conditions. We will clarify this in the text and in the presentation of Figure S6.

"Line 345- It might be helpful to remind the reader that Samalas is somewhere between NH and SYMM."

We will add a note to the revised text. Thank you.

Line 364 "[rivers] are a useful variable in the context of monitoring since they integrate precipitation changes over time" – and space. I would have thought that rivers would be more useful in integrating precipitation changes over space than over time?

We agree; we will re-phrase the sentence. Thank you.

Lines 371-393- I feel that these paragraphs disproportionately emphasise the regions where streamflow increases, when it actually decreases in a lot of areas. Can you make it more balanced? Line 383-384 In ASYMMSH, "the ITCZ moves northward, resulting in reduced river flux in the Amazon sector and increases in the Niger of central/wester Africa" This is true for summer, but river flow decreases over the Niger in winter.

We emphasized increases just because there is previous literature that reports declines in riverflow following large eruptions, but we fully agree the discussion should be more balanced. We will modify the text to highlight both increases and decreases in river flow.

Line 407- is it worth mentioning that there are factors that affect d18O in the process of being incorporated into paleo archives from precipitation? Lines 426-417- could you outline briefly how the amount and temperature effects work and in which direction they affect d18O concentrations?

In this paper, we wish to avoid discussing/speculating on the proxy system itself (e.g., cave-specific sites, etc.), which is a further complication for paleoclimate. The aim here was to highlight the large-scale imprint on d18O in precipitation following volcanic eruptions.

We will add text to make clear the known d18O-T and d18O-P relationships. Thank you.

Line 455 "In regions where tropical South American precipitation does not exhibit very large changes, such in the NDJFM SYMM composites, temperature may explain much of the isotopic response, again consistent with findings in Colose et al. (2016)." Can you specify in which direction and how temperature affects the isotopic response?

As above, we will revise the manuscript to make this explicit. Thank you.

Line 470-1:- are the arrows the right way round for the LW fluxes? They seem to be the opposite way round to the SW ones.

There was a mistake in this section. We will modify the SW arrows. Thank you.

Line 509 “Moisture makes it more difficult for the tropical circulation to transport energy poleward”. How?

In the tropics, the latent heat flux is towards the Equator owing to the transport of moist air in the low-level branch of the Hadley circulation. The circulation that cools (warms) the deep tropics (subtropics) by adiabatic expansion (compressional heating) also carries latent heat equatorward.

Figure 1: It would be nice to be able to see the absolute size of the volcanoes as well as the hemispheric contrast in aerosol loading- can you put in an extra time series? At the moment a perfectly symmetrical eruption will not show up at all. The overlap between the red and black lines also makes it difficult to see how big the black lines are in some cases. Also- what does FSNTC stand for?

We agree. We will create a completely new figure 1 to also highlight the absolute size of the eruptions and remove line overlap.

FSNTC is the name of the clear-sky net shortwave flux (at TOA) diagnostic in the CESM (CAM) history fields. We will replace this for clarity.

Figure 2- I assume this is surface temperature? (Rather than temperature at a different level in the atmosphere?)

Yes− all temperature plots (except the latitude-pressure 3-D temperature figure in the supplemental) are for the surface. We will write this in a revised caption for clarity.

Figure 8 panel a- the legend is a bit small. Panels b and c- The colour of the thin lines is confusing because they are not that similar to their corresponding thick line- e.g. the thin orange lines look like they go with total AET rather than the dry component.
Also- what depth of ocean is this for? All of it? And: “Grey envelope corresponds to the total AET anomaly vs. latitude in a control simulation using 50 realizations of a composite formed from the same dates as the ASYMMNH results”- I am not sure I entirely understand what you mean by this- are there 50 control runs? If there is only one control run, how are there 50 realisations if the same dates are used each time?

Thank you for highlighting an error in the description. First, we will remove the climatological ocean heat transport curve, since it is not part of our study. The poleward heat transport was for the full ocean. We will make the colors of all lines on the anomaly plots consistent with those used on the climatology plot, and improve the legend size.

There is only one control run. The anomalous transport plots show the post-volcanic spread in AET and its dry/latent components (each line shows a different eruption after averaging over the ensemble member dimension). The grey envelope and rectangles in Figure 8b,c are there to illustrate that the post-volcanic response is typically larger than would be expected if the analysis were repeated on a control simulation. To do this, we selected 16 different two-year intervals (each expressed as an anomaly relative to the previous five years) in the 850-1850 C.E. period, and averaged those 16 anomaly fields together. This analysis produces a single line in the transport-latitude plane, which does not collapse to zero due to the finite averaging size. Averaging over a larger number of cases than 16 would suppress the spread further, essentially mimicking the effect of having a larger ensemble. The analysis is repeated 50 times, in each case with a random selection of years, in order to generate a spread in AET anomaly at each latitude. This is a benefit of a long control run.

The value we used should be the size of the actual ensemble for comparison, which was 14 in the discussion manuscript (for this figure). Since then, additional ensemble members have been released (now 17), so the analysis will be repeated and reflected in all plots and in the discussion. We will improve the caption and discussion.

Figure 9: Could panels a and b be on the same scales to make them more obviously comparable?

Yes, we will revise the figure. Thank you.

Supplement figure S7- You don’t mention what the box is showing.

Thank you, this is the Niño 3.4 domain. We will insert this in the figure caption.

Technical corrections: Line 226- you have missed Iles and Hegerl 2015 off the reference list at the end.
and,
Line 454 – “such >AS< in the NDJFM SYMM composites”

Thank you, we will modify the text and reference section accordingly.

We appreciate the time and effort by the referee in reviewing this manuscript. We will address all issues, as highlighted below (reviewer text in red):

Line 29-30: Revise "the isotopic composition of the ITCZ" to "the isotopic composition of precipitation in the ITCZ".

Thank you for the suggestion– we will modify the text.

Line 33-35: Revise the final sentence of the abstract ("for the testing of models against paleoclimate evidence.") to be more specific.

We will change to, "Our results highlight the need for the careful consideration of the spatial structure of volcanic forcing for interpreting volcanic signals in proxy records, and therefore in evaluating the skill of Common Era climate model output."

We will add an example figure in the supplementary along these lines for the Asian monsoon, which exhibits a different response to our northern or southern volcano categories.

Line 75 (and elsewhere): Revise reference "Adam et al., 2016, in press" to "Adam et al., 2016"

Thank you, we will update the reference.

Line 87: Remove semi-colon before references.

Thank you for noticing this. It looks like an extra parenthesis needs to be removed.

Line 89: Add "in" between "asymmetries" and "the".

Thank you, we will correct.

Line 189-190: Are the previous five seasons or five years used as a reference period? Both are mentioned.

We will clarify. Anomalies are always with respect to the same time of year evaluated (e.g., NDJFM is relative to the previous five NDJFM's), otherwise the seasonal cycle becomes part of the response. For figures showing the monthly evolution of some variable (e.g., Figure S6), anomalies are with respect to the previous five Januaries, Februaries, etc., or for annual-mean metrics (Figure 8-9) the reference period is the full 60-month interval prior to the eruption.

Line 268: Remove "that these results are consistent with", as it is unnecessary and diminishes the clarity of the sentence.

Thank you, we will re-word this part.

Line 281: “the ITCZ shift may result in” May result in or does result in? Has this been specifically evaluated in your analysis?
and,
Line 282-283: Rephrase “since the precipitation signal is strongest moving with the ITCZ”. Unclear what is meant here.

Yes, Figure 5 shows this. We will re-word the sentence with stronger language and clarity, but the answer has eruption/ensemble member dependence and so cannot be made into a general statement. More often than not, however, precipitation increases in the hemisphere-mean when the ITCZ moves toward it. The mean is strongly sensitive to what happens in the ITCZ domain itself (rather than e.g., extratropical precipitation changes) since the amplitude of the anomaly is very large, and located in the deep tropics where the grid cell areas are larger.

Line 291: Rephrase “and therefore we restrict the anomalous precipitation field to a single season” to “and therefore we restrict the anomalous precipitation field to the same season.”

Thank you for the improved edit.

Line 296-303: The reference to Fig. S8 is missing. I suggest revising or removing this paragraph, as it does not seem to add any new substantive information to the discussion.

Thank you for pointing out that we missed the reference, we will edit the paragraph to improve the presentation and connection to the animations.

Line 325: Replace “eruptions in Table 1, multiplied by 15 ensemble members” to “16 eruptions in Table 1, multiplied by 15 ensemble members”.
and,
Line 338: Suggest replacing “In addition” with “Consistent with the SST anomalies,”
and,
Lines 341-344: Suggest replacing “we argue that the El Niño tendency in CESM is a forced response in ASYMMNH but otherwise depends on the state of internal variability concurrent with a given eruption. This explains why no such ENSO response is associated with” with “we argue that the El Niño tendency in CESM is a forced response in ASYMMNH but otherwise depends on the state of internal variability concurrent with a given eruption, as no such ENSO response is associated with…”

Agreed with all recommendations. Thank you.

Lines 432: Rephrase or revise figure reference. Figure S5 shows that the NH-SH zonally precipitation asymmetry is correlated to the AOD gradient. It does not show a correlation between (18Op) and P.

This is correct, thank you. We will clarify this part of the paper.

Line 466-467 (Eqn 3): Derive this equation from first principles, or provide a description of how Eqn. 3 was derived (e.g. modify Eqn. 1 in Hwang and Frierson, GRL, 2010 to include the storage term).

Thank you, we will add references to justify the equation.

Lines 523-527: Is this data shown? If not, state as such.

We did show the anomalous latent energy flux (lines 523-524) in Figure 8. We did not explicitly show a regression between AETeq and EFE (524-527) and we will state this.

Lines 537-538: Unclear what is meant by “the anomalous precipitation response is still coherent”. Rephrase to clarify.
and,
Lines 552-553: Replace “regressing the different events in all three categories together” to “regressing the precipitation median against the AETeq for each eruption (after averaging over ensemble members)”.
and,
Lines 552-554: Cite which figure this data is taken from. Also add the equation of the regression lines and correlation coefficients in Fig. 9.

We agree with the above and will re-phrase and modify the text or figures accordingly.

Lines 565-574: It is unclear how to interpret the representation of the ITCZ shift presented in Eqn. 7 (and the relationship between the ITCZ shift and AHTeq) without a theoretically-constrained N. It doesn’t appear valid (or meaningful) to conclude that “energetically, it is quite easy to move the ITCZ”, given that “the slope of the relationship between ITCZ location and AETeq may vary by a factor of 4-5 depending on the relationship used”. Further explanation and discussion of this issue is needed here.

Thank you. We will elaborate in the revised text, but we agree that it is difficult to interpret the magnitude of ITCZ shifts in the absence of a well-defined ITCZ metric. However, several past papers have reported such numbers, and so here we are highlighting that the slope is sensitive to which metric one chooses. This is an attempt to illuminate prior discussions and interpretations rather than offer a “best” N, which may indeed turn out to not be a useful question.

Lines 574-575: The final sentence in this paragraph seems abrupt and out of place. Consider adding a few sentences or a paragraph to summarize the findings of the energy budget analysis.
Line 687: Replace “to” with “in”.
Line 690: Replace “Results shown” with “Results are shown”.
Lines 693-694: Replace “N=the number of events used in each category, consistent with the number of listed events in Table 1 (multiplied by 15 for CESM and 3 for GISS-E2).” with “N=the number of events used in each category (consistent with the number

of listed events in Table 1, multiplied by 15 ensemble members for CESM and 3 ensemble members for GISS-E2)."
Line 715: Replace "Ensemble/Eruption" with "Composite"
Lines 717-718: Replace "Lighter lines associated with the dry and latent components indicate the eruption spread, each averaged over 14 ensemble members." with "Lighter lines represent individual eruptions, each averaged over 14 ensemble members."
Fig. 2 and Fig. 4: Revise labels to be consistent with text. E.g. replace "North" and "South" with "ASYMMNH" and "ASYMMSH".
Fig. 9: Plot ITCZ shift on same y-axis range for each subplot for visual clarity. Add 1:1 line to bottom left plot for visual clarity. Add equation of regression lines and correlation coefficients to upper subplots and bottom left subplot.

We agree with all recommendations and will modify the text and figures. Thank you for the suggestions, and time spent to improve the language of the paper.

Hemispherically asymmetric volcanic forcing of tropical hydroclimate during the last millennium

Chris Colose 7/17/2016 11:04 PM
Deleted: and water isotopologue variability

Abstract

Volcanic aerosols exert the most important natural radiative forcing of the last millennium. State-of-the-art paleoclimate simulations of this interval are typically forced with diverse spatial patterns of volcanic forcing, leading to different responses in tropical hydroclimate. Recently, theoretical considerations relating the intertropical convergence zone (ITCZ) position to the demands of global energy balance have emerged in the literature, allowing for a connection to be made between the paleoclimate simulations and recent developments in the understanding of ITCZ dynamics. These energetic considerations aid in explaining the well-known historical, paleoclimatic, and modeling evidence that the ITCZ migrates away from the hemisphere that is energetically deficient in response to asymmetric forcing.

Here we use two separate general circulation model (GCM) suites of experiments for the Last Millennium to relate the ITCZ position to asymmetries in prescribed volcanic sulfate aerosols in the stratosphere and related asymmetric radiative forcing. We discuss the ITCZ shift in the context of atmospheric energetics, and discuss the ramifications of transient ITCZ migrations for other sensitive indicators of changes in the tropical hydrologic cycle, including global streamflow. For the first time, we also offer insight into the large-scale fingerprint of water isotopologues in precipitation ($\delta^{18}O_p$) in response to asymmetries in radiative forcing.

The ITCZ shifts away from the hemisphere with greater volcanic forcing. Since the isotopic composition of precipitation in the ITCZ is relatively depleted compared to areas outside this zone, this meridional precipitation migration results in a large-scale enrichment (depletion) in the isotopic composition of tropical precipitation in regions the

ITCZ moves away from (toward). Our results highlight the need for careful consideration of the spatial structure of volcanic forcing for interpreting volcanic signals in proxy records, and therefore in evaluating the skill of Common Era climate model output.

Chris Colose 7/8/2016 7:36 PM

Deleted: Our results highlight the need for careful consideration of the spatial structure of volcanic forcing for both impact assessments and for the testing of models against paleoclimate evidence.

1. Introduction

The ITCZ is the narrow belt of deep convective clouds and strong precipitation that develops in the rising branch of the Hadley circulation. Migrations in the position of the ITCZ have important consequences for local rainfall availability, drought and river discharge, and the distribution of water isotopologues (e.g., $\delta^{18}O$ and δD, hereafter simply referred to as water isotopes, with notation developed in section 3.3) that are used to derive inferences of past climate change in the tropics.

Meridional displacements of the ITCZ are constrained by requirements of reaching a consistent energy balance on both sides of the ascending branch of the Hadley circulation (e.g., Kang et al., 2008, 2009; Schneider et al., 2014). Although the ITCZ is a convergence zone in near-surface meridional mass flux, it is a divergence zone energetically. The stratification of the tropical atmosphere is such that moist static energy (MSE) is greater aloft than near the surface, compelling Hadley cells to transport energy in the direction of their upper tropospheric flow (Neelin and Held, 1987). If the system is perturbed with preferred heating or cooling in one hemisphere, the anomalous circulation that develops resists the resulting asymmetry by transporting energy from the heated to the cooled hemisphere. Conversely, meridional moisture transport in the Hadley circulation is primarily confined to the low-level equatorward flow, so the response of the tropical circulation to asymmetric heating demands an ITCZ migration away from the hemisphere that is energetically deficient. Since the mean circulation dominates the atmospheric energy transport (AET) in the vicinity of the equator, the recognition that the ITCZ is approximately co-located with the latitude where meridional column-integrated energy fluxes vanish has provided a basis for relating the mean ITCZ position to AET. We note that this perspective focused on atmospheric energetics is distinct from one that emphasizes sea surface temperature gradients across the tropics (Maroon et al., 2016).

Chris Colose 7/10/2016 5:19 PM
Deleted: , in press

This energetic framework has emerged as a central paradigm of climate change problems, providing high explanatory and predictive power for ITCZ migrations across timescales and forcing mechanisms (Donohoe et al., 2013; McGee et al., 2014; Schneider et al., 2014). It is also a compelling basis for understanding why the climatological annual-mean ITCZ resides in the northern hemisphere (NH); it has been shown that this is associated with ocean heat transport, which in the prevailing climate is directed northward across the equator (Frierson et al., 2013; Marshall et al., 2014). The energetic paradigm also predicts an ITCZ response for asymmetric perturbations that arise from remote extratropical forcing. This phenomenon is exhibited in many numerical experiments, is borne out paleoclimatically, and has gradually matured in its theoretical articulation (Chiang and Bitz, 2005; Brocolli et al., 2006; Kang et al., 2008, 2009; Yoshimori and Brocolli, 2008, 2009; Chiang and Friedman, 2012; Frierson and Hwang, 2012; Bischoff and Schneider, 2014; Adam et al., 2016).

Chris Colose 7/8/2016 7:37 PM
Deleted: , in press

Thus far, however, little or only very recent attention has been given to the relation between transient ITCZ migrations and explosive volcanism (although see Iles et al., 2014; Liu et al., 2016, section 2). This connection has received recent consideration using carbon isotopes in paleo-records (Ridley et al., 2015) or in the context of volcanic and anthropogenic aerosol forcing in the 20th century (Friedman et al., 2013; Hwang et al., 2013; Allen et al., 2015; Haywood et al., 2015). The purpose of this paper is to use the energetic paradigm as our vehicle for interpreting the climate response in paleoclimate simulations featuring explosive volcanism of varying spatial structure.

Much of the existing literature highlighting the importance of spatial structure in volcanic forcing focuses on the problem of tropical vs. high-latitude eruptions and dynamical ramifications of changing pole-to-equator temperature gradients (e.g., Robock, 2000; Stenchikov et al., 2002; Shindell et al., 2004; Oman et al., 2005, 2006; Kravitz and Robock, 2011), which is a distinct problem from one focused on inter-hemispheric asymmetries in the volcanic forcing. Furthermore, episodes with preferentially higher aerosol loading in the southern hemisphere (SH) have received comparatively little attention, probably due to the greater propensity for both natural or anthropogenic aerosol forcing to be skewed toward the NH.

Here we show that it matters greatly over which hemisphere the aerosol loading is concentrated and that this asymmetry in aerosol forcing has a first-order impact on changes in the tropical hydrologic cycle, atmospheric energetics, and the distribution of the isotopic composition of precipitation.

2. Methods

To illuminate how the spatial structure of volcanic forcing expresses itself in the climate system, we call upon two state-of-the-art models that were run over the pre-industrial part of the last millennium, nominally 850-1850 C.E. (hereafter, LM), the most recent key interval identified by the Paleoclimate Model Intercomparison Project Phase 3 (PMIP3). An analysis of this time period is motivated by the fact that volcanic forcing is

Chris Colose 7/8/2016 8:40 PM
Deleted: (

the most important radiative perturbation during the LM (LeGrande and Anchukaitis, 2015; Atwood et al., 2016). Furthermore, the available input data that defines volcanic forcing in CMIP5/PMIP3 feature a greater sample of events, larger radiative excursions, and richer diversity in their spatial structure than is available over the historical period. This allows for a robust composite analysis to be performed over this interval.

The two GCM's that we use as our laboratory are NASA GISS ModelE2-R (hereafter, GISS-E2) and the Community Earth System Model Last Millennium Ensemble (CESM LME, hereafter, just CESM). The GISS-E2 version used here is the same as the non-interactive atmospheric composition physics version used in the CMIP5 initiative (called 'NINT' in Miller et al., 2014). CESM is a community resource that became available in 2015 (Otto-Bliesner et al., 2016), employing version 1.1 of CESM that consists of several component models each representing different aspects of the Earth system; the atmospheric component is the Community Atmosphere Model version 5 (CAM5, see Hurrell et al., 2013), which in CESM features 1.9° latitude x 2.5° longitude horizontal resolution with 30 vertical levels up to ~2 hPa. The GISS-E2 model is run at a comparable horizontal resolution (2° x 2.5°) and with 40 vertical levels up to 0.1 hPa.

Both GISS-E2 and CESM feature multiple ensemble members that include volcanic forcing. There are only a small number of volcanic eruptions in our different forcing classifications (see below) in each 1000 year realization of the LM, motivating an ensemble approach to sample multiple realizations of each eruption. There are currently 18 members in CESM, including 13 with all transient forcings during the LM and five volcano-only simulations. This number is much higher than the number of ensembles used for participating LM simulations in CMIP5/PMIP3. The volcanic reconstruction is

based on Gao et al., (2008, hereafter, G08) and the ensemble spread is generated from round off differences in the initial atmospheric state (~10^{-14} °C changes in the temperature field). Sampling many realizations of internal variability is critical in the context of volcanic eruptions given the different trajectories that can arise in the atmosphere-ocean system in response to a similar forcing (Deser et al., 2012).

For GISS-E2, there exist six available members that include a transient volcanic forcing history. Here, however we use only the three simulations that utilize the G08 reconstruction. This was done in order to composite over the same dates as the CESM events, and because the other volcanic forcing dataset that NASA explored in their suite of simulations (Crowley and Unterman, 2013) only provides data over four latitude bands, complicating inferences concerning hemispheric asymmetry. Taken together, there are 21,000 years of simulation time in which to explore the post-volcanic response while probing both initial condition sensitivity and the structural uncertainty between two different models. The three GISS-E2 members also differ in the combination of transient solar/land-use histories employed, but since our analysis focuses only on the immediate post-volcanic imprint, the impact of these smaller amplitude and slowly varying forcings is very small. We tested this using the composite methodology developed below on no-volcano simulations with other single forcing runs (in CESM) or with combined forcings (in GISS-E2) and found the results to be indistinguishable from that of a control run (not shown).

In both GISS-E2 and CESM, the model response is a slave to the spatial distribution of the imposed radiative forcing, which was based on the aerosol transport model of G08, rather than the coupled model stratospheric wind field, thus losing

potential insight into the seasonal dependence of the response that may arise in the real world. For our purpose, however, this is a more appropriate experimental setup, since the spatial structure of the forcing is implicitly known (Figure 1).

The original G08 dataset provides sulfate aerosol loading from 9 km to 30 km (at 0.5 km resolution) for each 10° latitude belt. This reconstruction is based on sulfate peaks in ice cores and a model of transport that determines the latitudinal, height, and time distribution of the stratospheric aerosol. In CESM, aerosols are treated as a fixed size distribution in three levels of the stratosphere, which provide a radiative effect, including shortwave scattering and longwave absorption. The GISS-E2 model is forced with prescribed Aerosol Optical Depth (AOD) from 15-35 km, based on a linear scaling with the G08-derived column volcanic aerosol mass (Stothers, 1984; Schmidt et al., 2011), with a size distribution as a function of AOD as in Sato et al (1993) – thus altering the relative long wave and shortwave forcing (Lacis et al, 1992; Lacis, 2015).

Chris Colose 7/8/2016 4:00 PM
Deleted: The stratospheric sulfate aerosol loadings given by G08 are a function of latitude, altitude and month.

We note that the GISS-E2 runs forced with the G08 reconstruction in CMIP5/PMIP3 were mis-scaled to give approximately twice the appropriate AOD forcing, although the spatial structure of forcing in the model is still coherent with G08. For this reason, we emphasize the CESM results in this study. However, we still choose to examine the results from the GISS-E2 model for two reasons. First, we view this error as an opportunity to explore the climate response to a wider range of hemispheric forcing gradients, even though it comes at the expense of not being able to relate the results to actual events during the LM. Secondly, the GISS-E2 LM runs were equipped with interactive water isotopes (section 3.3). A self-consistent simulation of the isotope field in a GCM is important, since it removes a degree of uncertainty in the error-prone conversion of isotopic signals into more fundamental climate variables. To our knowledge, an explicit simulation of the isotopic distribution following asymmetries in volcanic forcing has not previously been reported.

In our analysis, we classify volcanic events as "symmetric" (SYMM), and "asymmetric" ($ASYMM_X$), where the subscript X refers to a preferred forcing in the Northern Hemisphere (NH) or Southern Hemisphere (SH). Composites are formed from all events within each of the three classifications in order to isolate the volcanic signal. All events must have a global aerosol loading $>$ 8 Tg (1 teragram = 10^{12} g) averaged over at least one five-month period to qualify as an eruption and enter the composite. For comparison, the 1991 Mt. Pinatubo eruption remains elevated at ~20-30 Tg sulfate aerosol in the G08 dataset for about a year, and drops off to $<$1 Tg after 4-5 years.

Events fall into the SYMM category if they have less than a 25% difference in aerosol loading between hemispheres, while the $ASYMM_{NH}$ events have an at least 25% higher loading in the NH relative to the SH. The opposite applies to events falling into the $ASYMM_{SH}$ category. The dates for which these thresholds are satisfied are taken from the original G08 dataset (Table 1), and thus the CESM and GISS-E2 composites are formed using the same events despite the GISS-E2 mis-scaling and other differences in model implementation.

Results are reported for the boreal warm season (averaged over the MJJAS months) and cold season (NDJFM), except for annual-mean results in Figures 8-9, or for showing the progression of signals at monthly resolution (Figure S6, S9-S12). For each eruption, we identify the post-volcanic response by averaging the number of consecutive seasons during which the above criteria are met, typically 1-3 years. All seasons for an eruption lasting longer than one year are first averaged together to avoid over-weighting its influence in the composite. Anomalies are with respect to the corresponding time of year during the five years prior to the eruption. For overlapping eruptions, the five years prior to the first eruption are used instead. This relatively short reference period allows creating composites that are unaffected by changes in the mean background state due to low-frequency climate change during the LM. Composites for the SYMM, $\mathrm{ASYMM}_{\mathrm{NH}}$, and $\mathrm{ASYMM}_{\mathrm{SH}}$ cases are then obtained for each season and model by averaging over all anomaly fields within the appropriate classification, including all ensemble members. A two-sided Student's t-test was applied to all composites in order to identify regions where the anomalous signal is significantly different ($p < 0.05$) from the mean background conditions.

Chris Colose 7/8/2016 8:55 PM
Deleted: We use the previous five seasons as a reference period to calculate an anomaly for each event

In no case does the classification of a given eruption change over the duration of the event, with the exception of the largest eruption (Samalas, 1258 C.E.), which straddles the 25% asymmetry criterion (SYMM and $\mathrm{ASYMM}_{\mathrm{NH}}$) throughout the years following the event. This eruption would project itself most strongly onto the symmetric composite but may reasonably be classified as $\mathrm{ASYMM}_{\mathrm{NH}}$ due to the greater absolute aerosol loadings in the NH. Due to this ambiguity, we omit the Samalas event from our main results. We note that there are far more asymmetric eruptions during the LM based on our criteria than SYMM cases, most of which easily meet the two thresholds outlined above. Because of this, the classification assigned to each event is quite robust to slightly different criteria in defining the ratio (or differences) in hemispheric aerosol loading. Since the asymmetric composites are formed from a relatively large number of events, our results are insensitive to the addition or removal of individual eruptions that may be

Chris Colose 7/9/2016 3:45 PM
Deleted: results

more ambiguous in their degree of asymmetry. However, the SYMM composites are formed from only a few events, and are therefore more sensitive to each of the individual eruptions that are included.

We stress that in this study we are agnostic concerning the actual location of individual LM eruptions. Although aerosols from high-latitude eruptions tend to be confined to the hemisphere in which the eruption occurs, tropical eruptions may also lead to an asymmetric aerosol forcing, as happened during the eruptions of El Chichón and Mt. Agung during the historical period. The timing, magnitude, and spatial footprint of LM eruptions are important topics of research (see e.g., an updated reconstruction from Sigl et al., 2015), and our composite should strictly be interpreted as a self-consistent response to the imposed forcing in the model.

Similar approaches of stratifying volcanic events during the LM have only begun to emerge in the literature (e.g., Liu et al., 2016). Iles and Hegerl (2015) showed the CMIP5 multi-model mean precipitation response to a few post-1850 eruptions, emphasizing the spatial structure of the aerosols (see their supplementary Figure S14) but noted that it would be desirable for a greater sample of events in order to group by the location of the aerosol cloud. The LM provides an appropriate setting for this. Additionally, we add to these results by presenting a simulation of the water isotope distribution following different volcanic excursions. We emphasize that we are screening events by spatial structure and since different magnitude eruptions enter into the different composites, a quantitative comparison of the different event classifications (or the two models) is not our primary objective and would require a more controlled experiment. Instead, we are reporting on the different composite responses as they exist in current LM

simulations, and highlight the emergent structure that arises from different choices in how eruptions are sorted, much of which is shown to be scalable to different eruption sizes and robust to choices of model implementation.

3. Results

3.1) Temperature, Precipitation and ENSO response

Figure 2 illustrates the composite temperature anomaly for each classification and season in the CESM model. In both the ASYMM$_{NH}$ and ASYMM$_{SH}$ cases, the hemisphere that is subjected to the strongest forcing is preferentially cooled. In the ASYMM$_{NH}$ results, the cooling peaks over the Eurasian and North American continents. As expected, there tends to be a much larger response over land, as well as evidence of NH winter warming in the mid-to-high latitudes, a phenomenon previously highlighted in the literature and often associated with increased (decreased) pole-to-equator stratospheric (mid-tropospheric) temperature gradients (Figure S1) and a positive mode of the Arctic/North Atlantic Oscillation (Robock and Mao, 1992, 1995; Stenchikov et al., 2002; Shindell et al., 2004; Ortega et al., 2015). This effect is weak in the ASYMM$_{NH}$ composite, likely because the maximal radiative forcing is located in the NH, offsetting any dynamical response, but is present in the SYMM and ASYMM$_{SH}$ composites in both models (see Figure S2 for the GISS-E2 composite).

In the SH, cooling is muted by larger heat capacity associated with smaller land fraction, with weak responses over the Southern Ocean while still exhibiting statistically significant cooling in South America, South Africa, and Australia in all cases. In fact, the cooling in the ASYMM_{SH} composites is largely confined to the tropics, in contrast to the polar amplified pattern that is common to most climate change experiments. The cooling in all categories is communicated vertically (Figure S1) and across the free tropical troposphere, suggesting AET toward the forced hemisphere (section 3.4) for asymmetric forcing.

The cooling in the GISS-E2 model (Figure S2), displays a very similar spatial structure to CESM in all categories but with much greater amplitude due to the larger forcing. We note that the composite-mean forcing is similar between the four asymmetric panels, but larger in the symmetric cases. In Figure 3, we show the hemispheric and global average temperature response for both models after normalizing each event by a common global aerosol mass excursion, thereby accounting for differences in the average forcing among the different eruptions. This is done to highlight spread associated with internal variability and model differences, and assumes the response pattern scales linearly to global forcing, which is unlikely to be true across all events and for the two models. Nonetheless, the gross features of the hemispheric contrast and reduction in global-mean temperature are shared between both models.

The CESM precipitation response is shown in Figure 4 (Figure S3 for GISS-E2). For both the ASYMM_{NH} and ASYMM_{SH} cases, the ITCZ shows a robust displacement away from the forced hemisphere. The precipitation reduction in the SYMM composites is much less zonally coherent, instead featuring tropical-mean reductions in precipitation and a slight increase toward the subtropics (see also Iles et al., 2013; Iles and Hegerl, 2014). Despite global cooling and reduced global evaporation (not shown), the ITCZ shift

in $ASYMM_{NH}$ and $ASYMM_{SH}$ tends to result in precipitation increases in the hemisphere that is least forced (Figure 5), since the hemispheric-mean precipitation signal is largely influenced by the ITCZ migration itself.

The ensemble spread in precipitation for a selected eruption (1762 C.E., NDJFM) is shown in Figure S4, corresponding to the Icelandic Laki aerosol loading (a large $ASYMM_{NH}$ event). We note that the Laki eruption in Iceland actually occurred in 1783 C.E., but is earlier in our composite due to an alignment error in the first version of the G08 dataset. Results are shown for the 1763 C.E. boreal winter only (the full composite also includes 1762, see Table 1; Figure S4 also reports the winter 1763 Niño 3.4 anomaly in surface temperature for each ensemble member, and therefore we restrict the anomalous precipitation field to the same season). The ITCZ shift away from the NH is fairly robust across the ensemble members, particularly in the Atlantic basin, although internal variability still leads to large differences in the spatial pattern of precipitation, notably in the central and eastern Pacific.

The monthly time-evolution of the composite temperature and precipitation responses for the $ASYMM_{NH}$ and $ASYMM_{SH}$ cases can be viewed in an animation (Figures S9-S12). The global and hemispheric difference in aerosol loadings is also shown for each timestep (at monthly resolution) in the animations. When averaged over the individual eruptions within each classification, the global aerosol mass loading remains elevated above 8 Tg for nearly two years, coincident with the peak temperature and precipitation response that begins to dampen out gradually and relaxes back to pre-eruption noise levels after ~4-5 years. The seasonal migration of anomalous precipitation in the ITCZ domain occurs in nearly the same sense as the meridional movement of

climatological rainfall, highlighting important connections between the timing of the eruption relative to the seasonal cycle of rainfall at a given location.

In both CESM and GISS-E2, the ITCZ shift is approximately scalable to eruption size. For both models, we define a precipitation asymmetry index, PAi (Hwang and Frierson, 2013) in each season as the area-weighted NH tropical precipitation minus SH tropical precipitation (extending to 20° latitude) normalized by the model tropical-mean precipitation, i.e.,

$$PAi = \frac{P_{EQ-20°\mathrm{N}} - P_{20°\mathrm{S}-EQ}}{P_{20°\mathrm{S}-20°\mathrm{N}}} \quad (1)$$

Supplementary Figure S5 illustrates the relationship between PAi and the AOD gradient between hemispheres (AOD is inferred for the CESM model by dividing the aerosol loading by 75 Tg in each hemisphere, an approximate conversion factor to compare the results with GISS-E2). The mis-scaling in GISS-E2 results in a wider range of AOD gradients than occurs in CESM. Both models feature more tropical precipitation in the NH (SH) during boreal summer (winter) in their climatology, with more asymmetry in CESM during boreal summer. Interestingly, the most asymmetric events in GISS-E2 (those that result in equatorward precipitation movements) can be sufficient to produce more precipitation in the tropical winter hemisphere, thus competing with the seasonal insolation cycle in determining the seasonal precipitation distribution.

The meridional ITCZ shift leads to a number of important tropical climate responses. For example, an intriguing feature of the temperature pattern in Figure 2 is the El Niño response that is unique to the $\mathrm{ASYMM_{NH}}$ composites. This is unlikely to be a residual feature of unforced variability, since there are 288 events in the ASYMM$_{NH}$ composites (16 eruptions in Table 1, multiplied by 18 ensemble members), significantly more than in the other categories. The GISS-E2 temperature composite (Fig. S2) also features a relatively weak cooling for ASYMM$_{NH}$, despite the very large radiative forcing. The relationship between ENSO and volcanic eruptions has, historically, been quite complicated due to the problem of separating natural variability from the forced response, and due to a limited sample of historical eruptions where ENSO events were already underway prior to the eruption. Older studies have suggested that El Niño events may be more likely 1 to 2 years following a large eruption (e.g., Adams et al., 2003; Mann et al., 2005; Emile-Geay et al., 2008). Our findings are also consistent with recent results (Pausata et al., 2015) that found an El Niño tendency to arise from a Laki-like forcing (in that study, a sequence of aerosol pulses in the high latitudes that was confined to the NH extratropics), and was recently explored in CESM LME by Stevenson et al. (2016). Pausata et al. (2015) attributed the El Niño development directly to a southward ITCZ displacement. Since low-level converging winds are weak in the vicinity of the ITCZ, a southward ITCZ displacement leads to weaker easterly winds (a westerly anomaly) across the central equatorial Pacific. This was shown for a different model (NorESM1-M) and experimental setup, but also emerges in the ASYMM$_{NH}$ composite results for CESM. Indeed, a composite anomaly of ~ 0.5°C emerges over the Niño 3.4 domain, lasting up to two years (Figure S6) with peak anomalies in the first two boreal winters after an eruption. Consistent with the SST anomalies, a relaxation of the zonal winds and re-distribution of water mass across the Pacific Ocean can be observed in the ASYMM$_{NH}$ composite response (Figure S7).

Since the ITCZ shift is a consequence of differential aerosol loading, we argue that the El Niño tendency in CESM is a forced response in ASYMM$_{NH}$ but otherwise depends on the state of internal variability concurrent with a given eruption, as no such ENSO response is associated with the composite SYMM or ASYMM$_{SH}$ composites, although we note that El Niño does tend to develop in response to the Samalas eruption that was removed from our composite, and would strongly influence the interpretation of the SYMM results due to the few events sampled (not shown, though see Stevenson et al., 2016). However, we also caution that this version of CESM exhibits ENSO amplitudes much larger than observations, and also features strong El Niño events with amplitudes that are ~2 times larger than strong La Niña events even in non-eruption years. Therefore, we choose not to further explore the dependence of our results on ENSO phasing.

Because the ITCZ responds differently to the three eruption classifications, there are implications for best practices in assessing the skill of climate model output against proxy evidence. For example, Anchukaitis et al. (2010) noted discrepancies between well-validated tree-ring proxy reconstructions of eruption-induced drought in the Asian monsoon sector and the precipitation response following volcanic eruptions derived from the NCAR CSM 1.4 millennial simulation. However, we note that monsoonal rainfall responds differently to ASYMM$_{NH}$, ASYMM$_{SH}$, or SYMM events in both GISS-E2 and CESM. Figure S8 shows a histogram of boreal summer (MJJAS) Asian-Pacific rainfall anomalies for all events in both models. ASYMM$_{NH}$ and SYMM eruptions generally lead to reductions in rainfall over the broad region averaged from 65°-150°E, 10°-40°N (see also the spatial patterns in Figure 4 for CESM and Figure S3 for GISS E2-R). Because of

the southward ITCZ shift in ASYMM_{NH}, the most pronounced precipitation reductions occur for events within this category. In contrast, for ASYMM_{SH} events, the northward ITCZ shift and associated monsoon developments are such that precipitation changes are relatively muted, and often the anomalies are positive.

3.2) *River outflow*

An ITCZ shift away from the forced hemisphere will manifest itself in several other components of the tropical hydroclimate system that are important to consider from the standpoint of both impacts as well as the development of testable predictions. One such important component of the hydrologic cycle is global streamflow, a variable that is related to excessive or deficient precipitation over a catchment. Rivers are important for ecosystem integrity, agriculture, industry, power generation, and human consumption. Streamflow anomalies associated with volcanic forcing in observations and models have previously been documented for the historical period (Trenberth and Dai, 2007; Iles and Hegerl, 2015). Here, we discuss this variable in the context of our symmetric and asymmetric composites.

Chris Colose 7/17/2016 10:22 PM
Deleted: tends to correlate with

Chris Colose 7/17/2016 10:21 PM
Deleted: , and are a useful variable in the context of monitoring since they integrate precipitation changes over time

The hydrology module of the land-component of CESM simulates surface and subsurface fluxes of water, which serve as input into the CESM River Transport Model (RTM). The RTM was developed to route river runoff downstream to the ocean or marginal seas and enable closure of the hydrologic cycle (Oleson et al., 2010). The RTM is run on a finer grid (0.5° x 0.5°) than the atmospheric component of CESM.

Figure 6 shows the river discharge anomalies in our different forcing categories. The southward ITCZ shift in $ASYMM_{NH}$ results in enhanced discharge in central and southern South America, especially in the southern Amazon and Parana River networks. These territories of South America, along with southern Africa and Australia are the primary regions where land precipitation increases in the tropics for $ASYMM_{NH}$, and the river flow in these areas tends to increase. Our results are also consistent with Oman et al. (2006), who argue for a reduced Nile River level (northeastern Africa) following several large high northern latitude eruptions, including Laki and the Katmai (1912 C.E.) eruption. Their results were viewed through the lens of weakened African and Indian monsoons associated with reduced land-ocean temperature differences; our composite results suggest that regional precipitation reductions may also be part of a zonally coherent precipitation shift.

In $ASYMM_{SH}$, the ITCZ moves northward, resulting in reduced river flux in the Amazon sector and increases (reduction) in the Niger of central/western Africa during boreal summer (boreal winter). Interestingly, the Nile flow is also reduced in this case, although to a lesser extent, despite very modest precipitation increases during MJJAS for a southern hemisphere biased aerosol forcing. There are also modest discharge increases in southern Asia. However, there is simply very little land in regions where northward ITCZ shifts result in enhanced precipitation, suggesting less opportunity for increases in discharge to a SH biased eruption. For the SYMM eruptions, river discharge is reduced nearly everywhere in the tropics, consistent with the precipitation reductions that occur (Figure 3). The response is weaker or even reversed in the subtropics, such as in southern South America, where precipitation tends to increase (Iles and Hegerl, 2015).

3.3) *Water isotopic variability*

Another important variable that integrates several aspects of the tropical climate system is the isotopic composition of precipitation. Here, we focus on the relative abundance of $^{1}H_2{}^{18}O$ versus the more abundant $^{1}H_2{}^{16}O$, commonly expressed as $\delta^{18}O$, such that:

$$\delta^{18}O_p \equiv \left\{ VSMOW^{-1}\frac{O_{mp}^{18}}{O_{mp}^{16}} - 1 \right\} \times 1000 \qquad (2)$$

where O_{mp}^{18} and O_{mp}^{16} are the moles of oxygen isotope in a sample, in our case precipitation (denoted by the subscript mp). Delta values are with respect to the isotopic ratio in a standard sample, the Vienna Standard Mean Ocean Water (VSMOW= 2.005×10^{-3}).

$\delta^{18}O_p$ is a variable that is directly obtained from many paleoclimate proxy records. Therefore, rather than relying on a conversion of the local isotope signal to some climate variable, the explicit simulation of isotopic variability is preferred for generating potentially falsifiable predictions concerning the imprint associated with asymmetric volcanic eruptions. Indeed, $\delta^{18}O_p$ variability is the result of an interaction between multiple scales of motion in the atmosphere, the temperature of air in which the condensate was embedded, and exchange processes operating from source to sink of the parcel deposited at a site.

Water isotope tracers have been incorporated into the GISS-E2 model's atmosphere, land surface, sea ice and ocean, and are advected and tracked through every stage of the hydrologic cycle. A fractionation factor is applied at each phase change and all freshwater fluxes are tagged isotopically. Stable isotope results from the lineage of GISS-E2 models have a long history of being tested against observations and proxy records (e.g., Vuille et al., 2003; Schmidt et al., 2007; LeGrande and Schmidt, 2008, 2009).

Figure 7 shows the $\delta^{18}O_p$ response in the GISS-E2 model. Seasonal calculations are weighted by the precipitation amount for each month, although changes in the seasonality of precipitation are not important in driving our results (not shown). The literature on mechanistic explanations for isotope variability has a rich history of being described by several "effects" such as a precipitation amount effect in deep convective regions or a temperature effect at high latitudes (Dansgaard, 1964; Araguás-Araguás et al., 2000), so named as to reflect the most important climatic driver of isotopic variability at a site or climate regime. Notably, $\delta^{18}O_p$ tends to be negatively correlated with precipitation amount in the deep tropics and positively correlated with temperature at high latitudes (see e.g., Hoffman and Heimann, 1997 for a review of mechanisms). However, isotope-climate relations are generally complex. In our experiments, the $\delta^{18}O_p$ spatial pattern in the tropics (Figure 7) exhibits a similar pattern to precipitation changes induced by the ITCZ shift (Figure S5 for GISS-E2), particularly over the ocean. The meridional movement of the ITCZ leads to an isotopic signal that is more positive (enriched in heavy isotopes) in the preferentially forced hemisphere. The hemisphere toward which the ITCZ is displaced on the other hand experiences increased tropical

rainfall and a relative depletion of the heavy isotope (more negative $\delta^{18}O_p$). Thus, the paleoclimatic fingerprint of asymmetric volcanic eruptions is characterized by a tropical dipole pattern, with more positive (negative) $\delta^{18}O_p$ associated with reduced (increased) rainfall.

Over land, South America stands out as exhibiting a palette of isotopic patterns depending on forcing category and season. The South American monsoon system peaks in austral summer, and the largest precipitation reductions occur in $ASYMM_{SH}$ when the ITCZ moves northward. There is a dipole pattern, characterized by isotopic enrichment (depletion) in ^{18}O in the northern (southern) tropics of South America in $ASYMM_{NH}$ during NDJFM, while the opposite pattern emerges in $ASYMM_{SH}$, both associated with Atlantic and east Pacific ITCZ displacements. During the austral winter, climatological South American precipitation peaks in the northern part of the continent, and precipitation in this region is reduced in both the SYMM and $ASYMM_{SH}$ composites, leading to a large increase in $\delta^{18}O_p$. This is consistent with recent results in Colose et al. (2016), who used the isotope-enabled GISS-E2 model to form a composite of all large (AOD > 0.1) LM tropical volcanic events based on the Crowley and Unterman (2013) dataset. The eruptions analyzed in that study were smaller in amplitude due to differences in the scaling during implementation, as well as the fact that G08 tends to have larger volcanic events in the original dataset to begin with. In regions where tropical South American precipitation does not exhibit very large changes, such as in the NDJFM SYMM composites, temperature may explain much of the isotopic response, again consistent with findings in Colose et al. (2016).

3.4) Atmospheric Energetics

The overarching purpose of this work was to consider the influence of asymmetric volcanic forcing on the energetic paradigm outlined in section 1. This framework of analyzing ITCZ shifts in the context of asymmetric forcing predicts a net AET anomaly toward the hemisphere that is preferentially forced by explosive volcanism, with anti-correlated dry and latent energy fluxes both contributing to drive the ITCZ away from the forced hemisphere. To examine this relationship in CESM, we first write a zonal-mean energy budget for the atmosphere (Trenberth, 1997; Donohoe and Battisti, 2013):

$$\frac{1}{2\pi a^2 cos\phi}\frac{\partial AET}{\partial \phi} = ASR_{TOA} - OLR_{TOA} + SW_{sfc}^{\uparrow} - SW_{sfc}^{\downarrow} + LW_{sfc}^{\uparrow} - LW_{sfc}^{\downarrow} + LH_{sfc} + SH_{sfc} + L_f Sn - \frac{1}{g}\int_0^{p_s} \frac{\partial\left(c_p T + L_v q + k\right)}{\partial t}\, dp \qquad (3)$$

where ASR_{TOA} is the absorbed solar radiation, OLR_{TOA} is outgoing longwave radiation at the top of the atmosphere (TOA), $SW_{sfc}^{\uparrow}$ is reflected surface shortwave radiation, $SW_{sfc}^{\downarrow}$ is shortwave received by the surface (sfc), $LW_{sfc}^{\uparrow}$ is longwave radiation emitted (or reflected) by the surface, $LW_{sfc}^{\downarrow}$ is longwave radiation received by the surface, LH is the latent heat flux, SH is the sensible heat flux, Sn is snowfall rate, q is specific humidity, k is kinetic energy, ϕ is latitude, a is the radius of the Earth, T is temperature, c_p is specific heat capacity, L_v and L_f are the latent heats of vaporization and fusion, p is

pressure (p=p_s at the surface), and g is the acceleration due to gravity. All terms are defined positive into the atmosphere, and the subscripts denote top-of-atmosphere (TOA) or surface flux (sfc) diagnostics. Equation 3 effectively calculates MSE transport (section 1) as a residual of energy fluxes in the model.

The last term ($\partial/\partial t$) on the right side of equation 3 is the time-tendency term, representing storage of energy in the atmosphere (hereafter, $STOR_L$ and $STOR_D$ for latent and dry energy, respectively. The time-derivative is calculated using finite differencing of the monthly-mean fields. The term in the parentheses is the moist enthalpy, or MSE minus geopotential energy. The kinetic energy is calculated in this study but is several orders of magnitude smaller than other terms, and hereafter is folded into the definition of $STOR_D$). The tendency term must vanish on timescales of several years or longer, but is important in our context. We explicitly write out the snowfall term since CESM (and any CMIP5 model) does not include surface energy changes associated with snow melt over the ice-free ocean as part of the latent heat diagnostic, and must be calculated to close the model energy budget.

Integrating yields an expression for the atmospheric heat transport across a latitude circle:

$$AET(\phi) = 2\pi a^2 \int_{-\frac{\pi}{2}}^{\phi} \left(R_{TOA} + F_{sfc} - STOR_L - STOR_D\right) \cos\phi \, d\phi \quad (4)$$

where we have combined the TOA terms into R_{TOA} and the snowfall and surface diagnostics have collapsed into a single variable F_{sfc}. Similarly, the latent heat flux $\mathcal{H}_L$ across a latitude circle is:

$$\mathcal{H}_L(\phi) = 2\pi a^2 \int_{-\frac{\pi}{2}}^{\phi} \left(LH_{sfc} - L_v P - STOR_L\right) \cos\phi \, d\phi \quad (5)$$

where P is precipitation in kg m^{-2} s^{-1}. We note that transport calculations are presented for CESM and were done for only 17 ensemble members, since there are missing output files for the requisite diagnostics in one run.

Figure 8a shows the annual-mean climatological northward heat transport in CESM, as performed by the atmosphere, in addition to the dry and moisture-related components of AET. The total CESM climatological poleward transport is in good agreement with observational estimates (e.g., Trenberth and Caron, 2001; Wunsch, 2005; Fasullo and Trenberth, 2008), peaking at ~5.0 PW and ~5.2 PW in the SH and NH subtropics, respectively (1 petawatt = 10^{15} W). In CESM, the SH receives slightly more net TOA solar radiation than the NH (by ~1.3 W m^{-2} in the annual-mean), and the NH loses slightly more net TOA longwave radiation to space (by ~0.89 W m^{-2}). However, the CESM annual ocean heat transport is northward across the equator (not shown), keeping the NH warmer than the SH by ~0.98 °C. As a consequence, AET is directed southward across the equator (red line). Moisture makes it more difficult for the tropical circulation to transport energy poleward, and the transport of moisture in the low-level equatorward flow is directed northward across the equator and associated with an annual-mean ITCZ approximately co-located with the atmospheric energy flux equator (EFE), the latitude where AET vanishes. This arrangement of the tropical climate is consistent with satellite and reanalysis results for the present climate (Kang and Seager, 2012; Frierson et al., 2013).

In response to asymmetric volcanic forcing, anomalous AET is directed toward the preferentially forced hemisphere (Figure 8b,c), along the imposed temperature gradient. Results are shown for the annual-mean AET anomaly in $\mathrm{ASYMM_{NH}}$ and $\mathrm{ASYMM_{SH}}$ for one year beginning with the January after each eruption, although averaging the first 2-3 years yields similar results with slightly smaller amplitudes. The equatorial AET ($\mathrm{AET_{eq}}$) anomaly averaged over all events and ensemble members for $\mathrm{ASYMM_{NH}}$ ($\mathrm{ASYMM_{SH}}$) is approximately 0.08 (-0.06) PW, defined positive northward, with much larger near-compensating dry and latent components. The anomalous moisture convergence drives the ITCZ shift away from the forced hemisphere. Anomalies in $\mathrm{AET_{eq}}$ when considering each unique volcanic event (after averaging over the 17 ensemble members) are strongly anti-correlated with changes in the energy flux equator (r = -0.97, not shown), the latitude where AET vanishes.

The change in cross-equatorial energy transport for the SYMM ensemble/eruption mean (not shown) does not exhibit the coherence of the asymmetric cases for either AET or the individual dry and moist components, and in all cases does not emerge from background internal variability.

Quantifying the ITCZ shift is non-trivial, since the precipitation field is less sharply defined than the EFE, and climate models (including the two discussed here) exhibit a bimodal tropical precipitation distribution (often called a "double-ITCZ"), often with one mode of higher amplitude in the NH (centered at 8°-9 °N in CESM). However, despite pervasive biases that still exist in the climatology of tropical precipitation in CMIP5 (e.g., Oueslati and Bellon, 2015), the anomalous precipitation response is still characterized by a well-defined ITCZ shift (or a shift in the bimodal precipitation

distribution, e.g., Figure 9 in Stevenson et al., 2016) and the gross features presented here are in agreement with theoretical considerations. In our analysis, a movement in the latitude of maximum precipitation is not found to be a persuasive indicator of our ITCZ shift. In fact, the meridional shift is better described as a movement in the center of mass of the precipitation distribution, including changes in the relative amplitude of the two modes (e.g., a heightening of the SH mode for a southward ITCZ shift). Different metrics to describe the shift in the center of mass have been presented in the literature (e.g., Frierson and Hwang, 2012; Donohoe et al., 2013; Adam et al., 2016).

Here, we first adopt the precipitation median ϕ_{med} definition (e.g., Frierson and Hwang, 2012) defined as the latitude where area-weighted precipitation from 20°S to ϕ_{med} equals the precipitation amount from ϕ_{med} to 20°N, i.e., where the following is satisfied:

$$\int_{20°S}^{\phi_{med}} P\cos(\phi)\,d\phi = \int_{\phi_{med}}^{20°N} P\cos(\phi)\,d\phi \qquad (6)$$

When considering the spread across eruption size (regressing the different events in all three categories together after averaging over ensemble members) we find a movement of ~ -8.9° shift in ITCZ latitude per 1 PW of anomalous AET_{eq} (Figure 9). The sign of this relationship is a robust property of the present climate system, although it is higher than other estimates (Donohoe et al., 2013) that analyzed the ITCZ scaling with AET_{eq} to a number of other time periods and forcing mechanisms (not volcanic), including the seasonal cycle, CO_2 doubling, Last Glacial Maximum, and mid-Holocene.

Chris Colose 7/21/2016 10:30 PM
Deleted: 4.7

Chris Colose 7/23/2016 5:17 PM
Deleted: it is slightly

It was argued in that paper that the ITCZ is “stiff” in the sense that a large AET_{eq} is required to move the ITCZ. However, the sensitivity of this relationship may vary considerably depending on ITCZ metric considered (Figure 9 presents a scaling with different indices), based on the following equation (Adam et al., 2016):

$$\phi_{ITCZ} = \frac{\int_{20°S}^{20°N} \phi \, (P \cos(\phi))^N \, d\phi}{\int_{20°S}^{20°N} (P \cos(\phi))^N \, d\phi} \qquad (7)$$

Here, N controls the weighting given to the modes in the precipitation distribution. Typically ϕ_{ITCZ} moves toward the precipitation maximum as N increases, but importantly, the sensitivity of a ϕ_{ITCZ} migration to a given anomaly in AET_{eq} also changes. Figure 9 shows the regression of anomalous ϕ_{med} and ϕ_{ITCZ} ($N = 5$) against anomalous AET_{eq}. (r= -0.94). ϕ_{ITCZ} ($N = 3$) yields a high correlation (r = -0.95) and best follows a 1:1 line with the EFE (Figure 9, bottomleft). The slope of the relationship between ITCZ location and AET_{eq} may vary by a factor of 4-5 depending on the relationship used. For example, there is approximately a -11.7° shift in ITCZ latitude per 1 PW of anomalous AET_{eq} using ϕ_{ITCZ} ($N = 3$). Thus, we interpret our results as suggesting that energetically, it is not necessarily difficult to move the ITCZ, and urge caution in characterizing past ITCZ shifts as being difficult to reconcile with paleo-forcing estimates (Donohoe et al., 2013). Indeed, as many studies have used a “precipitation centroid” or a similar variant to quantify tropical precipitation migrations, we recommend exploring the sensitivity of ITCZ shifts to different ways of characterizing the movement in precipitation mass unless the community can agree upon

4. Conclusions

In this work, we have examined two models, NASA GISS ModelE2-R and the recently completed CESM Last Millennium Ensemble, and stratified volcanic events by their degree of asymmetry between hemispheres. We find a robust ITCZ shift away from the preferentially forced hemisphere, as a consequence of adjustments in the Hadley circulation that transports anomalous energy into the cooled hemisphere.

An important component of our work was using the GISS-E2 model to explicitly simulate the oxygen isotopic imprint following major volcanic eruptions with asymmetric aerosol forcing. The ITCZ shift following asymmetric forcing leads to a more positive isotopic signal in the tropical regions the ITCZ migrates away from, and a relative depletion in heavy isotopes in regions the ITCZ migrates to. These results provide a framework for the search of asymmetric volcanic signals in high-resolution isotopic or other temperature and precipitation sensitive proxy data from the tropics.

There is still considerably uncertainty in the timing and magnitude of LM eruptions. Improvements in particle size representation have been identified as critical target for improved modeling and comparisons to proxy data (e.g., G. Mann et al., 2015). Here, we argue that the inter-hemispheric asymmetry of the aerosol forcing also emerges as being of first-order importance for the expected volcanic response. Future developments in model-proxy comparisons should probe the uncertainty space not just in the global-mean radiative forcing and coincident internal variability at the time of the eruption, but also the spatial structure of the aerosol cloud. For example, simulations that represent volcanic forcing simply as an equivalent reduction in total solar irradiance at the TOA are unrealistic and cannot be expected to be faithful to tropical climate proxy records.

We hope this contribution will help motivate the connection between the spatial structure of volcanic episodes and the expression on tropical hydroclimate as an urgent paleoclimate target in future studies and model intercomparisons. Such investigation also calls for high-resolution and accurately dated tropical proxy networks that reach across hemispheres. Developments in seasonally and annually resolved volcanic reconstructions from both hemispheres (Sigl et al., 2015) are of considerable importance in such assessments. Future modeling efforts that are forced with the explicit injection of volcanic species, while also probing multiple realizations of internal variability that will dictate the spatio-temporal evolution of the volcanic aerosol, are also urgently required as a tool for understanding both past and future volcanic impacts.

Supplemental Figure Captions

Figure S1. Zonal-mean temperature anomalies as a function of atmospheric pressure and latitude in CESM volcanic eruption composites for each event and season classifications discussed in text.

Figure S2. GISS spatial composite of temperature anomaly (°C) for (top row) $ASYMM_{NH}$, (middle row) $ASYMM_{SH}$, and (bottom row) SYMM events, each in (left column) NDJFM and (right column) MJJAS. Note that scaling of colorbar is different from CESM composite (Figure 2).

Figure S3. As in Figure S2, except for precipitation (mm/day). Note colorbar range difference compared to CESM composite (Figure 4).

Figure S4. Precipitation anomaly (mm/day) for the 1763 C.E. Laki eruption for NDJFM. Results displayed for all 18 ensemble members in CESM relative to the 1757-1761 C.E. NDJFM mean. Surface air temperature anomalies (°C) averaged over the Niño 3.4 region displayed at topright of each panel. Note colorbar range difference compared to CESM all-event composite (Figure 4).

Figure S5. Precipitation asymmetry index (unitless) as defined in text vs. NH minus SH AOD gradient (hemispheric sulfate loadings divided by 75 Tg for the CESM results). Results displayed for both seasons in LM time series. Since most of the LM time series features zero or low volcanic activity, all seasons where $-0.1 <$ AOD gradient < 0.1 are shown by dashed box and whisker (GISS) and solid box only (CESM). The whisker lengths are very similar between the two models, and were omitted to avoid visual overlap. Results presented for the 18 and 3-member ensemble mean for each season, which suppresses the variability (represented by the box and whisker spread) for the non-

eruption compilation but allows for comparison with the ensemble-mean volcanic responses.

Figure S6. Niño 3.4 SST anomalies for all ASYMM$_{NH}$ events, centered on Year 0 (the January before each eruption). The mean SST anomaly averaged over all eruption and ensemble members is shown as red line, and the eruption spread is shown as gray shading (after averaging 18 ensemble members). Composite-mean NH aerosol loading (Tg), aligned in the same way, is shown as purple line.

Figure S7. Composite Sea Surface Height (cm) and surface wind anomalies for ASYMM$_{NH}$ events. Composite formed from the boreal winter events in Table 1 in main text. Blue box shows the Niño 3.4 region.

Figure S8. Distribution of precipitation anomalies (mm/day) in CESM (top) and GISS-E2 (bottom) during MJJAS averaged broadly over the Asian-Pacific monsoon sector (65°-150°E, 10°-40°N), including regions of the Indian summer monsoon, western North Pacific summer monsoon, and the East Asian summer monsoon. Each eruption is taken to be an independent event, and there are more events in CESM due to the greater ensemble size (note difference in y-axis scale and slightly different bin width). Solid lines correspond to a normal distribution for the (red, ASYMM$_{NH}$; blue, ASYMM$_{SH}$; black, SYMM) events.

Figure S9. Animation from May of Year -2 to December of Year +6 (as discussed in text) of monthly temperature anomalies (°C) associated with ASYMM$_{NH}$ volcanic forcing in CESM. For each time step, the global aerosol loading (in Tg) and hemispheric

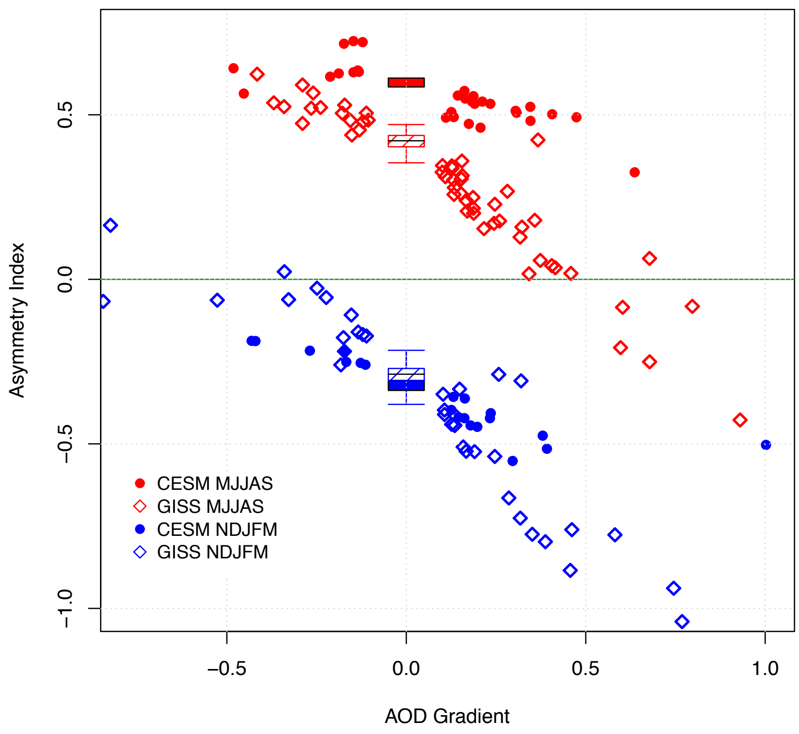

Figure S5. Precipitation asymmetry index (unitless) as defined in text vs. NH minus SH AOD gradient (hemispheric sulfate loadings divided by 75 Tg for the CESM results). Results displayed for both seasons in LM time series. Since most of the LM time series features zero or low volcanic activity, all seasons where -0.1 <AOD gradient < 0.1 are shown by dashed box and whisker (GISS) and solid box only (CESM). The whisker lengths are very similar between the two models, and were omitted to avoid visual overlap. Results presented for the 18 and 3-member ensemble mean for each season, which suppresses the variability (represented by the box and whisker spread) for the non-eruption compilation but allows for comparison with the ensemble-mean volcanic responses.

CESM LME uses the Parallel Ocean Program (POP2; Smith et al. 2010) as the ocean model component. This is where the sea surface temperature (SST) and sea surface height (SSH) diagnostics presented in Figure S6 and S7 are calculated. The model features 384 (latitude) x 320 (longitude) ocean grid points, with variable horizontal resolution that increases toward the tropics. There are 60 vertical levels, gradually increasing from 10 m resolution in the top 150 m to ~250 m below 3 km depth.

To perform a superposed epoch analysis for the state of the Pacific following all ASYMM_{NH} events, the Niño 3.4 index is calculated for each ensemble member in CESM (averaging the SST from 120°W-170°W, 5°S-5°N) with the long-term annual cycle removed. "Year 0" corresponds to the January before each eruption. We only show results for ASYMM_{NH}, since no distinguishable behavior in the Niño 3.4 time series is exhibited for the other eruption classifications, as discussed in text. Months before Year 0 may feature a non-zero aerosol loading (as in Figure S6) due to the 8 Tg threshold for defining an eruption not being satisfied, or due to overlap with previous eruptions. Unlike the spatial composites discussed in the main text, pre-eruption months presented below are not replaced with the pre-eruption dates of previous overlapping eruptions. However, in the composite-mean, the aerosol loading is negligible for pre-eruption years, as well as after ~5 years after the composite eruption, and does not bias the results.

Figure S6 presents the Niño 3.4 time series averaged over all ASYMM_{NH} eruptions and ensemble members. Grey shading corresponds to the eruption spread after averaging over the ensemble members. Since the CESM ENSO amplitude is large, even after averaging over 18 members, the pre-eruption envelope is still quite wide (individual

events may be on the order of 5°C above normal). Averaging over fewer ensemble members would progressively increase the width of the envelope.

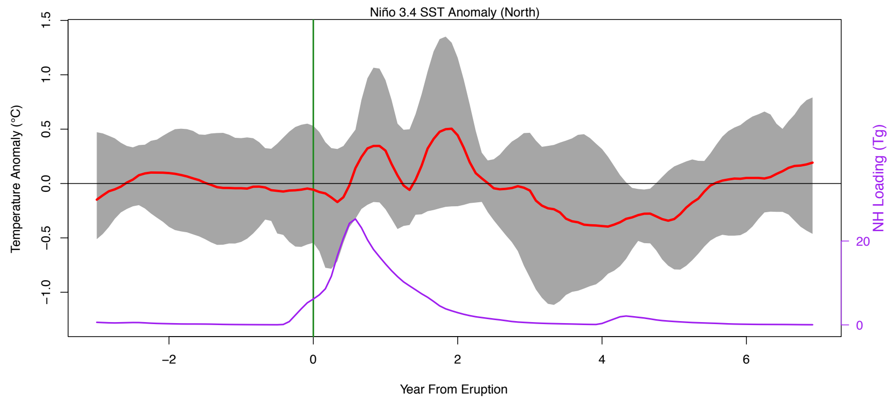

Figure S6. Niño 3.4 SST anomalies for all $ASYMM_{NH}$ events, centered on Year 0 (the January before each eruption). The mean SST anomaly averaged over all eruption and ensemble members is shown as red line, and the eruption spread is shown as gray shading (after averaging 18 ensemble members). Composite-mean NH aerosol loading (Tg), aligned in the same way, is shown as purple line.

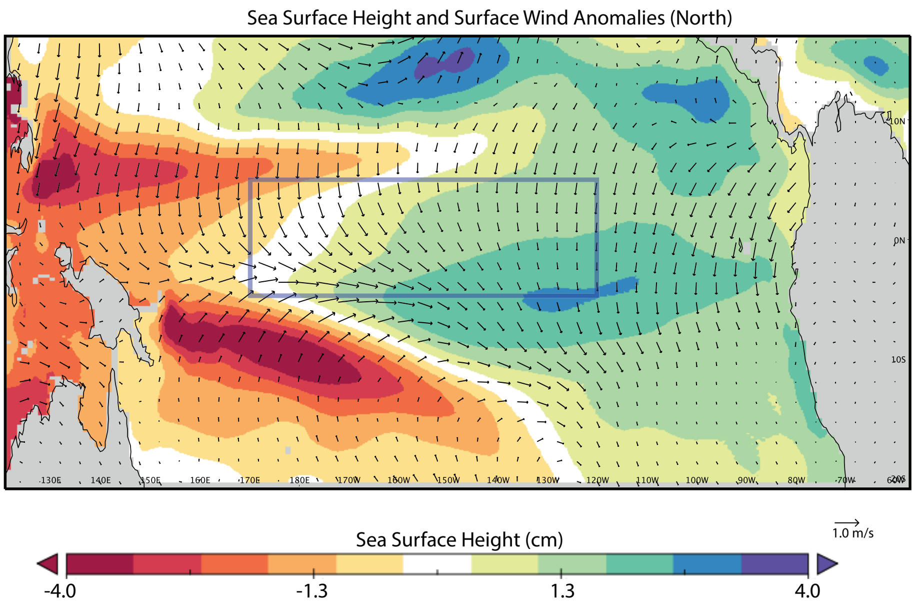

Figure S7. Composite Sea Surface Height (cm) and surface wind anomalies for ASYMM$_{NH}$ events. Composite formed from the boreal winter events in Table 1 in main text. Blue box shows the Niño 3.4 region.

Chris Colose 7/17/2016 11:18 PM
Deleted: . Blue box shows the Niño 3.4 region

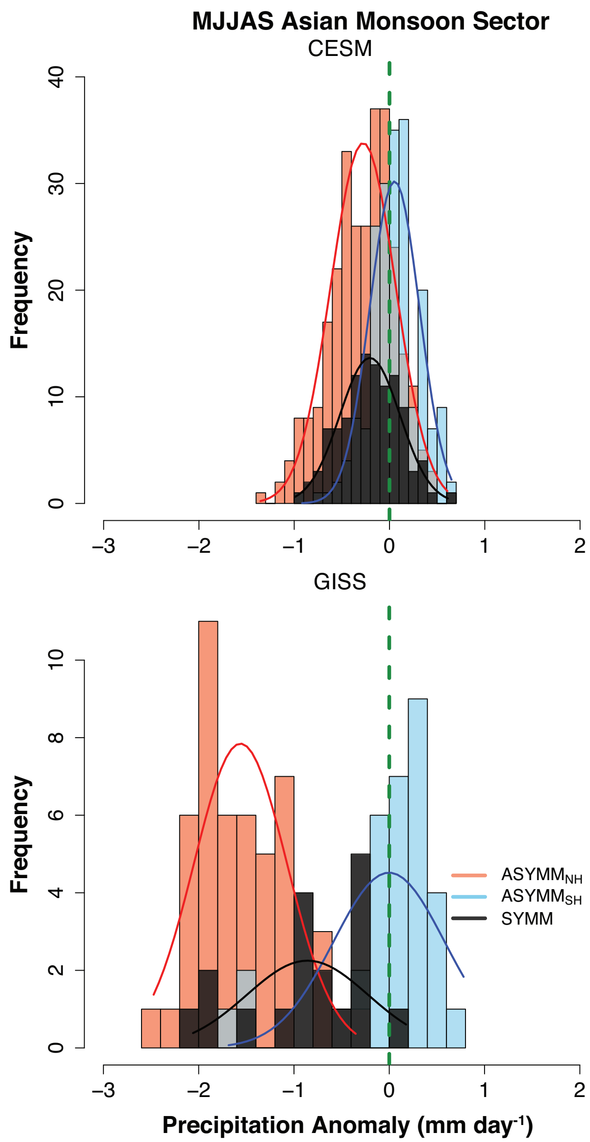

Figure S8. Distribution of precipitation anomalies (mm/day) in CESM (top) and GISS-E2 (bottom) during MJJAS averaged broadly over the Asian-Pacific monsoon sector (65°-150°E, 10°-40°N), including regions of the Indian summer monsoon, western North Pacific summer monsoon, and the East Asian summer monsoon. Each eruption is taken to be an independent event, and there are more events in CESM due to the greater ensemble size (note difference in y-axis scale and slightly different bin width). Solid lines correspond to a normal distribution for the (red, ASYMM$_{NH}$; blue, ASYMM$_{SH}$; black, SYMM) events.

In the animations below, monthly temperature and precipitation anomalies from CESM (for each event, using five years as a pre-eruption reference period) are shown in a loop from May of Year -2 to December of Year +6, where year 0 and month 1 corresponds to the January before each eruption, defined based on the same criteria as in main text. The animation shows the average anomaly field for all eruptions among 18 ensemble members, which suppresses the internal variability in pre-eruption months. There is still variability in the sequence of pre-eruption composites due to the finite number of realizations of natural variability, non-zero aerosol loading (only when the 8 Tg global aerosol loading is exceeded is an event aligned with Year 0), overlap with previous eruptions, in addition to non-volcanic radiative forcings that are still present in 13/18 of the ensemble members.

Figure S9. Animation from May of Year -2 to December of Year +6 (as discussed in text) of monthly temperature anomalies (°C) associated with $ASYMM_{NH}$ volcanic forcing in CESM. For each time step, the global aerosol loading (in Tg) and hemispheric difference in loading (NH minus SH) are displayed. Months exceeding the 8 Tg global aerosol loading in the G08 dataset are displayed in red.
