7 **Abstract.** The shipping sector is a significant contributor to emissions of air pollutants in marine and coastal
8 regions. In order to achieve sustainable shipping, primarily through new regulations and techniques, greater
9 knowledge of dispersion and deposition of air pollutants is required. Regional model calculations of the dispersion
10 and concentration of sulphur, nitrogen and particulate matter, as well as deposition of oxidized sulphur and
11 nitrogen from the international maritime sector in the Baltic Sea and the North Sea have been made for the years
12 2011 to 2013. Contribution from shipping is highest along shipping lanes and near large ports for concentration
13 and dry deposition. Sulphur is the most important pollutant coupled to shipping. The contribution of both SO₂
14 concentration and dry deposition of sulphur represented up to 80% of the total in some regions. WHO guidelines
15 for annual concentrations were not trespassed for any analysed pollutant, other than PM_{2.5} in the Netherlands and
16 Belgium, and central Poland. But due to the resolution of the numerical model, 50 x 50 km², there may be higher
17 concentrations locally close to intense shipping lanes. Wet deposition is more spread and less sensitive to model
18 resolution. The contribution of wet deposition of sulphur and nitrogen from shipping was up to 30% of the total
19 wet deposition. Comparison of simulated to measured concentration at two coastal stations close to shipping lanes
20 showed some underestimations and missed maximums, probably due to resolution of the model and
21 underestimated ship emissions.

22
23 Changed regulation for maximum sulphur content in maritime fuel, in 2015 from 1% to 0.1%, decreases the
24 atmospheric sulphur concentration and deposition significantly. But due to costs related to refining, the cleaning
25 of exhausts through scrubbers has become a possible economic solution. Open-loop scrubbers meet the air quality
26 criteria but their consequences for the marine environment are largely unknown. The resulting potential of future
27 acidification in the Baltic Sea, both from atmospheric deposition and from scrubber water along the shipping lanes,
28 based on different assumptions about sulphur content in fuel, scrubber usage and increased shipping density has
29 been assessed. The increase in deposition for different shipping and scrubber scenarios differs for the basins in the
30 Baltic Sea, with highest potential of acidification in the southern basins with high traffic. The proportion of ocean
31 acidifying sulphur from ships increases when taking scrubber water into account and the major reason to increasing
32 acidifying nitrogen from ships are due to increasing ship traffic. Also with the implementation of emissions control
33 for nitrogen, the effect of scrubber on acidification is evident. This study also generates a database of shipping and
34 scrubber scenarios for atmospheric deposition and scrubber exhaust from the period 2011 to 2050.

35
36 *Keywords:* Sulphur dioxide, nitrogen dioxide, nitrogen oxides, particulate matter, EMEP model, deposition,
37 shipping, air pollutants, scrubber, Baltic Sea region.

1 **1 Introduction**

2 Emissions of air pollutants is a large problem, air pollutants have harmful effects on human health, the environment
3 and buildings. They also influence climate and water quality (Seinfeld and Pandis, 2006; Monks et al., 2009;
4 Fuglestvedt and Berntsen, 2009). There has been a significant decrease in land based emissions over land areas in
5 Europe since the risks associated with high levels of air pollutants were brought into light two decades ago. During
6 the same time, however, emissions from shipping in the Baltic Sea and the North Sea have increased, with the
7 exception of a very recent decrease in sulphur emissions and successive emissions of particulate matter due to
8 regulations (Gauss et al., 2013; Jonson et al., 2015). Shipping is the most cost-effective option for global transport
9 of goods, and over 90% of the world trade is carried by sea (IMO, 2016). The Baltic Sea area is one of the busiest
10 shipping areas in the world and it is of great importance for the development and economy of the surrounding
11 countries. The intensity of shipping in the Baltic Sea has increased during the last decade and it is expected to
12 increase further in the coming years.

13
14 Shipping primarily generates emissions of nitrogen oxides (NO_x), sulphur dioxide (SO_2), carbon monoxide (CO),
15 carbon dioxide (CO_2), volatile organic compounds (VOC) and particulate matter (PM) (Corbett and Fischbeck,
16 1997; Eyring et al., 2010; Matthias et al., 2010). Maritime contribution of sulphur dioxide into the atmosphere is
17 mainly caused by the high sulphur content in the fossil fuels used by the sector (Eyring et al., 2005). Nitrogen
18 oxides include nitric oxide (NO) and nitrogen dioxide (NO_2), which are emitted from engines that operate under
19 high temperature and pressure (Eyring et al., 2010). Particulate matter from shipping consists of a complex mixture
20 of sulphate (SO_4), soot, metals and other organic and inorganic fragments (Winnes et al., 2014), the prime
21 component being sulphate, which is formed by oxidation of SO_2 (Eyring et al., 2010). The quantity and size of
22 particulate matter emitted from shipping depends mainly on the type of fuel and its sulphur content, as well as the
23 ship's engine (Fridell et al., 2008; Aardenne et al., 2013). Particulate matter is divided into PM_{10} and $\text{PM}_{2.5}$
24 in terms of its aerodynamic diameter where PM_{10} has an aerodynamic diameter less than 10 micrometres, while
25 $\text{PM}_{2.5}$ has a diameter less than 2.5 micrometres. SO_2 is also chemically transformed into sulphuric acid in the
26 presence of liquid water or water vapour and can cause acid rain which contributes to the acidification of the
27 oceans, lakes and soil. Sulphur and nitrogen from oxides are called oxidized sulphur, OXS, and oxidized nitrogen,
28 OXN, in deposition and both act as acidifying compounds.

29
30 Effects of air pollution vary in both space and time; they may be short-lived and local or more prolonged and
31 global (Seinfeld and Pandis, 2006). Exposure to particulate matter encompasses a variety of risks to human health,
32 primarily on the respiratory organs and the cardiovascular system (World Health Organization, 2006). Corbett et
33 al. (2007) estimated that shipping-related emissions of particulate matter contribute to approximately 60,000
34 deaths annually on a global scale, with impacts concentrated to coastal areas along the major trade routes. Further,
35 particulate matter may be absorbing or reflecting which has an impact on the Earth's radiation balance. The net
36 effect of emissions from the maritime sector on the radiation balance is negative, resulting in a cooling effect
37 (Eyring et al., 2005; Fuglestvedt and Berntsen, 2009). Jonson et al. (2015), hereafter abbreviated J15, estimated
38 that current emissions from shipping in the Baltic Sea region cause a life loss per person by 0.1–0.2 years, in areas
39 close to the main shipping lanes. Exposure to high levels of sulphur oxides cause health issues such as irritation to
40 respiratory system, lungs and eyes (World Health Organization, 2006). High levels of nitrogen in the atmosphere

1 also have negative impacts on human health, cause corrosion of materials and are included in the process of
2 degrading of methane (Fuglestad and Berntsen, 2009; Eyring et al., 2010). Deposition of nitrate contributes to
3 both eutrophication and acidification of water and soil. A pH reduction in the ocean causes worsening conditions
4 to a lot of marine ecosystems (Andersson et al., 2008). Hunter et al. (2011) modelled acidification from strong
5 acids in the North Sea, Baltic Sea and South China Sea. On an annual scale the trends were on the order of 10^{-4}
6 pH units per year, comparable to the global assessment by Doney et al. (2007). Hassellöv et al. (2013) modelled
7 pH decrease from shipping, worldwide, on the seasonal scale. In areas with heavy ship traffic and seasonal
8 stratification of the surface water gave larger pH decrease, comparable to the effects from CO₂ uptake. Thus locally
9 the annual decrease is of the order of 0.002 pH units (Orr, 2011, Rhein et al. 2013). On the annual scale the results
10 from Hassellöv et al. (2013) is comparable with Hunter et al. (2011) and Doney et al. (2007). Acidification is a
11 major challenge in the Baltic Sea region today where the critical load is exceeded in big parts of the area (Gauss
12 et al., 2013). Due to its brackish water the Baltic Sea has a rather lower buffer capacity, and is thus more sensitive
13 to acidification (Andersen et al., 2010).

14

15 The maritime sector was, at least earlier, one of the least controlled sources of anthropogenic emissions. It is a
16 global cross-border sector with conditions making legislation challenging (Aardenne et al., 2013). The
17 International Maritime Organization (IMO) is the agency within the United Nations (UN) responsible for maritime
18 security and safety together with prevention of pollutants by ships (IMO, 2015). IMO has formulated The
19 International Convention on the Prevention of Pollution by Ships (MARPOL), which has been ratified globally
20 (CleanShip, 2013). MARPOL and its Annex VI regulate emissions from ships.

21

22 The regulations include the Sulphur Emission Control Area (SECA), which consists of the Baltic Sea, North Sea,
23 English Channel and North America's coastal areas (IMO, 2017; J15). Residual oil or High Sulphur Fuel Oil
24 (HSFO) can have up to 3.5% sulphur content, but a global mean estimate is 2.4% (IMO, 2009) to 2.7% outside
25 SECA (ENTEC, 2005). In the SECAs a number of reductions have been made. In May 2006 the sulphur content
26 in maritime fuel was restricted to 1.5% (percentage by mass) by refining to marine gas oil (MGO). In 2010, it was
27 reduced to 1.0% and according to J15, this reduction of sulphur had a positive effect on air quality and the
28 deposition of sulphur. A further reduction of the permitted level of sulphur to 0.1% was made in January 2015
29 (Aardenne et al., 2013). From 1 January 2020 the upper sulphur content should be reduced to 0.5% globally
30 (outside the SECAs) even if 2025 is a more probable outside EU (Jonson et al. 2015). The reduction in SECA has
31 led to extensive investment in scrubbers, or Exhaust Gas Cleaning Systems (EGCS), since the refined oil increases
32 in price. Scrubbers use seawater to remove the sulphur oxides generated from high-sulphur fuels. An expected
33 effect of open-loop scrubbers is that acidification is concentrated along the shipping lanes as the scrubber exhaust
34 is released into the water. With scrubbers the ships can still use HSFO and it seems that the 0.5% limit can be
35 walked around (S&P Global Platts, 2016).

36

37 There is currently no international regulation of direct particulate emissions from shipping. But with less sulphur,
38 also particle emissions will decrease, but since there are other sources as well, the decrease is less. The regulations
39 of nitrogen emissions in MARPOL (TIER) are defined as a function of year of installation and ship speed (IMO,
40 2007). The TIER I standard was implemented in 2000 and was 10% stricter than for ships built before 2000. The

1 introduction of TIER II in 2011 was up to 15% stricter than the former. As regulations only include newly produced
2 ships, the effects of regulations of nitrogen emissions from shipping have so far been small. There are also Nitrogen
3 Emission Control Areas (NECA), e.g. in the Caribbean Sea and along the North American coast, but so far, not in
4 the Baltic Sea and North Sea. However, at the end of 2016 it was decided that in 2021 a NECA will be introduced
5 for the Baltic Sea and North Sea. There are indications that with this introduction, emissions of NO_x will decrease
6 by 80% relative to the TIER I level (J15). In J15 it was assumed that half of the fleet followed the TIER III
7 commitment by 2030, and all in 30 years (2050). In addition to HSFO and low sulphur oil there are also other
8 possible fuels, like liquefied natural gas (LNG) and methanol.

9
10 J15 did a thorough study of air pollutants from shipping in the Baltic Sea and the North Sea. They used the EMEP
11 model (Simpson et al., 2012) and estimated the effects of present and future emissions of NO₂, SO₂ and particles
12 as PM10 and PM2.5, among other compounds. As ship emission data they used the ship traffic Emission
13 Assessment Model (STEAM) (Jalkanen et al., 2009, 2012). This model is based on movements of individual ships
14 with high temporal resolution (Automatic Identification System, AIS) together with engine times and
15 corresponding emission factors. The concentrations and depositions were analysed for the year 2010.
16 Concentrations were focused along the shipping routes but there was a significant spread for depositions. The
17 effect of the reduced sulphur content in the fuel made in 2010 and the effect of future scenarios with reduced
18 sulphur content (2015 value of 0.1%) and on regulation of NECA was also investigated.

19
20 The present study is to some extent similar to J15, we study deposition and near surface concentrations originating
21 from shipping, introducing also the estimation of the future effects from scrubbers in the Baltic Sea. We use the
22 same chemical transport model as J15, the EMEP model, although at a lower resolution, 50 x 50 km², compared
23 to 14 x 14 km². There are some differences compared to J15, we use default ship emission data for the EMEP
24 model whereas J15 use AIS based ship emissions. We analyse the present concentration due to ship emissions and
25 its deposition but focus on the sulphur exhausts in a future scenario relying on scrubber technique (defining
26 suggested scenarios for use of scrubbers). The model is run for five years (2009 to 2013) and by using scenarios
27 for future shipping and cleaning technologies, estimates of deposition (from air and scrubber) into the Baltic Sea
28 until 2050 are derived. The use and averaging of 3 years (2009–2011) for the present deposition fields reduces the
29 variability from meteorology for the future scenarios. The scenarios are limited to “worst case scenarios” regarding
30 the use of scrubbers, but the results will be discussed in relation to other possibilities. In the analysis of the period
31 around 2010 we examine the impact of having coarse resolution on concentration and deposition as well as using
32 non-AIS databases for ship emissions, when comparing our results to J15. Concentrations may, for instance be
33 very dependent on resolution whereas deposition may be less sensitive.

34 **2 Data**

35 **2.1 EMEP Model System**

36 The unified European Monitoring and Evaluation Programme (EMEP) is policy driven under the Convention on
37 Long-range Transboundary Air Pollution (CLRTAP) for international co-operation to solve transboundary air
38 pollution problems. The programme is divided into five centres working with emission inventories, measurements,

1 and chemical and dispersion modelling (<http://www.emep.int/>) The EMEP model is a chemical atmospheric
2 transport model (http://emep.int/mscw/index_mscw.html). The model is Eulerian and traditionally consists of a
3 three-dimensional grid that covers Europe. The standard horizontal resolution is approximately 50 km × 50 km at
4 60°N and has 20 layers in the vertical direction up to 100 hPa. Land use is separated into 16 classes. Emissions
5 included in the EMEP model are sulphur dioxide, nitrogen oxides, ammonia (NH₃), non-methane volatile organic
6 compounds (NMVOC), carbon monoxide and particulate matter. The model's lateral boundary concentrations
7 consist of a merging of observed data and results from global models. A more comprehensive description of the
8 EMEP model can be found in Simpson et al. (2012).

9
10 The EMEP model is considered to be a robust model for dispersion modelling in the atmosphere (Simpson et al.,
11 2012; Gauss et al., 2015). In Gauss et al., 2015 a comparison of model results from the EMEP model version rv.4.7
12 and observations of annual averages of concentrations at individual stations for 2013 were made. On average,
13 sulphur dioxide concentration was underestimated by 11%, nitrogen dioxide was underestimated by 7%, PM₁₀ was
14 underestimated by 28% and PM_{2.5} by 19%. Validation of wet and dry deposition of oxidized nitrogen and sulphur
15 based on approximately 30 test sites in 2013 shows, despite the limitations of the model, a relatively good
16 agreement with observed data considering a low bias and good correlation (Gauss et al., 2015).

17 **2.2 EMEP Model Data**

18 The meteorological input data used in the EMEP model are from the Integrated Forecast System (IFS) which is a
19 global forecast model run by the European Centre for Medium-Range Weather Forecasts (ECMWF). Chemical
20 data used in the EMEP model cover 56 persistent and 15 short-lived components, chemical reactions, phase
21 changes and solubility in water. Emission inputs consist of gridded yearly national emission data (Vestreng, 2003;
22 Simpson et al., 2012). The anthropogenic emissions are categorized in ten different groups called Selected
23 Nomenclature for reporting of Air Pollutants (SNAP). All nations in the EMEP-area are responsible for reporting
24 annual gridded emission data for each SNAP sector. National shipping is included in SNAP 8 (Other mobile
25 sources and machinery) and is a part of the emission data that each nation should report. International shipping is
26 also included in SNAP 8. International ship emission data used in the model were designed according to Table 1.
27 In EMEP model rv.4.4 ship emissions and their distributions were mainly ENTEC/IIASA inventory. ENTEC UK
28 Ltd. (now part of AMEC Environment Infrastructure, UK, www.amec-ukenvironment.com) compiled an emission
29 inventory for 2000 (ENTEC, 2002) based on Lloyd's Register (1998). In addition, data on ship activity in ports
30 were acquired using questionnaires (ENTEC, 2002). IIASA has updated these data in recent years with trends
31 (Cofala et al., 2007).

32
33 In the development of the data set in EMEP model version rv.4.8 new aspects, as SECA, the economic situation
34 and the using of different sizes of ships have been included. The emission data were designed for 2000 to 2011. In
35 order to supplement emission data for the following years, extrapolation with Centre on Emission Inventories and
36 Projections (CEIP) method were used. This interpolation was, however, shown to significantly underestimate the
37 2012 and 2013 emissions in the North Sea and in the Baltic Sea (Fagerli et al., 2015). Emissions from international
38 shipping are assumed to be constant throughout the day and year in the model (Simpson et al., 2012). This was
39 also shown by Jalkanen et al. (2014) being within 10% in the years 2006-2009.

1
2 Between model versions several changes that affect aerosol production/modelling have been implemented by the
3 EMEP community; e.g. modification of the sea salt parametrisation, changes in the standard aerosol surface area
4 and uptake rates, dust boundary conditions and an update of the split of particulate matter into elemental carbon,
5 organic matter and the remainder. Furthermore, biogenic emissions of dimethyl sulphide (DMS) have been
6 updated. Rather than being prescribed, DMS emissions are now calculated dynamically during the model
7 calculation and vary with meteorological conditions.

8
9 Comparing the emissions in rv.4.4 and 4.8 shows very small differences, on the order of less than 1%. However,
10 deposition and concentrations deviate significantly due to the new modifications of the chemistry and physics. Fig.
11 1 shows the relative change in 2011 (in %) going from rv.4.4 to 4.8 in deposition (from shipping) of oxidised
12 sulphur (OXS) and nitrogen (OXN), respectively. Overall, the depositions, has increased, but mostly over land,
13 and OXN in northern Atlantic and for OXS north of Great Britain. In Baltic Sea the increase is minor for OXS,
14 being less than 10%, but for OXN between 5 and 30%.

15

16 **2.3 Other data sources**

17 Historical ship emission data were taken from the global gridded EDGAR 4.2 dataset (Olivier et al. 2011), with a
18 horizontal resolution of 0.1° and available from 1970 to 2008 (<http://edgar.jrc.ec.europa.eu>). For the 1900–1969
19 period, the EDGAR–HYDE 1.3 dataset has a resolution of 1° (Van Aardenne et al., 2001). Both these datasets
20 contain global anthropogenic emissions of NO_x, SO₂, NH₃, and other species. The EDGAR-HYDE data are
21 derived from historical activity data from the 10 year interval Hundred Year Database for Integrated Environmental
22 Assessments (HYDE), 1890–1990. These data are based on the data and methodology of EDGAR 2.0 (Olivier et
23 al., 1996). Linear interpolation of the emissions was used to fill the gaps between the 10-y intervals of EDGAR–
24 HYDE 1.3.

25

26 For background emissions of SO₂, NO_x, and the deposition of OXS, OXN (i.e., from sources other than ship
27 traffic), output from the MATCH chemical transport model (Robertson et al. 1999) was used. We used a simulation
28 for the 1900–2050 period set up as described by Engardt and Langner (2013). Forcing was based on the RCP4.5
29 radiative scenario and accompanying anthropogenic emissions (Lamarque et al., 2010). Shipping emissions were
30 from Eyring et al. (2010) and the International Comprehensive Ocean-Atmosphere Data (ICOADS) spatial proxies
31 were used

32 **2.4 Measurements**

33 We validated the EMEP modelled data for 2013 using measured concentrations of nitrogen dioxide, sulphur
34 dioxide and particulate matter from stations Vavihill and Utö (Fig. 2). Data for Vavihill were downloaded from
35 the database of the Swedish Environmental Research Institute
36 (<http://www.ivl.se/sidor/omraden/miljodata/luftkvalitet.html>) and data for Utö were from the Finnish
37 Meteorological Institute's website (http://www.ilmanlaatu.fi/tarkistetut_tulokset/). The measuring station in
38 Vavihill is located in Svalöv municipality (N 56,142°; E 13,855°), 28 km from the port city of Helsingborg and 25

1 km from the coast of Øresund (Fig. 2). Within a radius of 10 km from the measuring station, no emission sources
2 that are assumed to have a significant impact on air quality are located. At the distance of 10 km from the measuring
3 station, there is a heavily trafficked road and within 50 km the larger cities of Lund and Malmö are located (Sjöberg
4 and Peterson, 2014; IVL Swedish Environmental Research Institute, 2015). The measuring station on Utö is
5 located in the central parts of the island (N 59,779°; E 21,394°), a few hundred m from the shore (Fig. 2). About
6 300 m away from the test site, there is a smaller shipping lane and a harbour for small boats. About 10 km west of
7 the measurement site, there is an international shipping lane that is heavily trafficked by larger vessels (Finnish
8 Meteorological Institute, 2015).

9 **3 Methods**

10 **3.1 EMEP Model Runs**

11 This investigation consists of two parts. A database with historical and future scenarios of emissions and
12 depositions of oxidized sulphur and nitrogen (the data base) was created. Model version rv.4.4 was used with
13 meteorology from the years 2009 to 2011 and emissions from 2011 (see sec 3.3). In the second part, the model
14 was validated to coastal measurements of concentrations for the year 2013 using the newer model version rv.4.8.
15 As seen in sec 2.2 rv.4.8 gives higher depositions of OXS and especially OXN. This is further discussed in sec 5.
16 Also the spatial pattern of concentration and deposition was analysed and compared to the results from J15. For
17 each studied year, two model runs in the EMEP model were made, a base run and a scenario run. In the base run,
18 all emission sources were included, and in the scenario run, the emissions from international shipping in the Baltic
19 Sea and North Sea, were excluded (SNAP 8). The scenario run was subtracted from the base run to obtain the
20 impact of the international maritime sector in the Baltic Sea and the North Sea.

21 **3.2 Model performance of concentrations**

22 Particulate matter is difficult to measure and various measuring instruments register different types of particles,
23 which result in some uncertainties to input data. Also, some semi-volatile compounds exist in both gaseous and
24 particle form and the definition of the different particle groups vary in different countries. Moreover, there are still
25 components of the coarser particles, such as aerosol and biogenic organic farming dust that are not included in
26 EMEP model. Another uncertainty of the input data is that not all nations included in the EMEP area report yearly
27 emissions (Gauss et al., 2015). We validated the EMEP modelled data for 2013 using measured concentrations of
28 nitrogen dioxide, sulphur dioxide and particulate matter from stations Vavihill and Utö.

29
30 Measured data were compared to daily averages of modelled data from the 50 km × 50 km grid box where the
31 measurement sites were localized. If measured data were specified in hourly values, calculations of daily averages
32 were made. When measured data were missing for one day, the validation for this day was excluded in the
33 evaluation. The evaluation included calculations of daily average, bias, correlation, root mean square error (RMSE)
34 and also the P-test and scatter plots of model results versus measured data of the daily average concentrations of
35 sulphur dioxide, nitrogen dioxide and particulate matter.

36 **3.3 Future Ship Emissions**

1 Five future scenarios differing with respect to the sulphur content of the fuel and scrubber usage of the shipping
2 fleet were developed (Table 2). Scenario no. 1 corresponds to the fuel content regulation January 2010 to December
3 2014 (1% sulphur in the fuel), and scenario no. 3 (0.1% sulphur in the fuel) corresponds to the regulations from
4 January 2015. Scenario no. 2 has been included since it in Sweden was suggested as an alternative, low-cost
5 reduction in sulphur content (0.5% sulphur in the fuel). In scenario 4 and 5, use of open-loop wet scrubber
6 technique for removing sulphur from the exhaust is assumed for 50 and 100% of the fleet respectively. The use of
7 scrubber is assumed to increase linearly from no scrubber installations at all. The increase rate of the proportion
8 of ships using scrubbers are the same for scenario 4 and 5 but ends at 50% or 100%, respectively. Hence, these are
9 similar until 2020. It is assumed that the fuel used in the ships with scrubbers will have an average low-cost sulphur
10 content of 2.7%, corresponding to the current average outside SECA (ENTEC, 2005). Further it is assumed that
11 the ships in the basins north from Baltic proper, Archipelago, Åland and Bothnian Seas and Bothnian Bay, cannot
12 use the scrubber technique to a large extent. This is due to the ice properties in the winter and the low alkalinity.
13 For scenarios 4 and 5 the emissions to the atmosphere are estimated to correspond to 0.1% sulphur in the fuel
14 (following the regulations). To achieve atmospheric emissions corresponding to 0.1% sulphur in the fuel it is
15 assumed that 96% of the sulphur is taken up in the scrubber, the scrubber water is discharged untreated and the
16 sulphur oxides are directly transformed into strong sulphuric acid. Regulations of nitrogen oxides emissions are in
17 an early stage. Therefore, these emissions are assumed to increase at the same rate as the shipping traffic. We here
18 follow the TREMOVE European transport model (De Ceuster et al., 2006), which gives an increase of 2.5% and
19 3.9% per year for cargo and passenger traffic, respectively. In addition, the effect of a NECA was studied,
20 following assumptions made in J15. There is no seasonal variation in ship emissions in the ENTEC/IIASA
21 inventory (2011) and the monthly variation through the years 2006–2009 presented by Jalkanen et al. (2014) is
22 rather low ($\pm 10\%$). Therefore, no seasonal variation in the future emissions is assumed.

24 **3.4 Deposition scenarios of ship emissions**

25 In Omstedt et al. (2015) a database for ship emissions and the corresponding depositions was constructed for the
26 1900–2011 period using a combination of emission databases (ENTEC/IIASA, EDGAR 4.2 and EDGAR-HYDE
27 1.3) and deposition from the EMEP model. For the years 2006–2009, the emission distribution was scaled to
28 correspond to that presented by Jalkanen et al. (2014); for 2010, linear interpolation was used. Ship traffic was
29 also assumed to follow the regulated changes in fuel sulphur content in the SECA area. We assume 2.7% sulphur
30 in the fuel until May 2006, 1.5% until the end of 2009, and 1% thereafter. This information was also used to correct
31 the EDGAR 4.2 emissions fields. Further back in time, the emission fields from 1900 to 1970 from EDGAR-
32 HYDE 1.3 were used.

33
34 We here extend the database into the future using the alternative scenarios described in Section 3.3. We also use a
35 similar methodology as in Omstedt et al. (2015), with the reference year 2011. The spatial distribution of
36 atmospheric deposition of sulphur oxides and nitrogen oxides from ship traffic was estimated by the EMEP model.
37 The model was first run for the meteorological years 2009 to 2011 with emissions from 2011. The variation of
38 deposition between the three years indicated that inter-annual effect of meteorology was low for annual deposition.
39 Initial analysis, to help find the better method revealed that dry deposition is more focused along ship routes than

1 wet deposition; the dry part of the deposition was thus assumed to be scaled by the local emissions. The wet
2 deposition was more spread. Local ship emissions accounted for approximately 25% of deposition in the central
3 Baltic Sea and approximately 45% of wet deposition in the Kattegat. In the Kattegat, almost half of the wet
4 deposition originated from North Sea ship traffic, whereas a very small proportion of the wet deposition in the
5 Baltic Sea east of Bornholm originated from the North Sea. Therefore, the wet deposition trends of sulphur oxides
6 and nitrogen oxides, in each basin, was set equal to the local emission, except for Kattegat, Belt Seas and Øresund,
7 where 50%, as a first-order approximation, was assumed to depend on emission trends in the North Sea. This
8 approach resulted in a reference year (2011) of deposition-to-emission ratios with a monthly resolution. The
9 relative seasonal variability was kept throughout the period.

10 Non-ship emission trends follow the RCP 4.5 scenarios from 2010 (Lamarque et al., 2010) and deposition
11 simulations (Engardt and Langner, 2013) using the MATCH model (Robertson et al., 1999). Ship emission from
12 RCP 4.5 (Eyring et al., 2010), including the traffic distribution from ICOADS (Wang et al., 2008), was replaced
13 by our scenarios described in Table 2. Total emissions were calculated by correspondingly correcting the MATCH
14 output. Last, the spatial fields were averaged into the Baltic Sea basins defined in Fig. 2.

16 **4 Results**

17 **4.1 Ship deposition scenarios**

18 2011 is the base year for the deposition scenarios. That means that the spatial relative distribution of ship effects
19 remains the same during the scenarios. Fig. 3 shows the ship emissions and spatial distribution of dry, wet and
20 total deposition in 2011. Even if the ship emissions remain constant throughout the year, the weather causes the
21 deposition pattern to change. In Fig. 4 the seasonal variations (mean of the meteorological years 2009–2011 and
22 emissions from 2011) of the deposition of OXS are shown in six Baltic Sea basins (Kattegat, Arkona, Bornholm,
23 Eastern Gotland, G. of Finland and Bothnian Bay basins). In most basins there is a minimum during the summer
24 and a maximum in the autumn.

25
26 The ship emissions scenarios in Baltic Sea are shown in Fig. 5. Emissions into the atmosphere (Fig 5a) all show
27 positive trends after 2015, due to the increasing traffic. With the traffic scenarios emissions have more than doubled
28 in 2050 compared to 2015. The reduction of sulphur content in fuel will, as expected, result in a reduction in
29 sulphur emissions into the atmosphere in the Baltic Sea area. With scrubber, the OXS goes directly into the water
30 along the shipping lines. Note that it is assumed that ships are not using scrubbers north of Baltic proper (as
31 discussed in section 3.3). Averaged over the whole complete Baltic Sea (Fig 5b) it is seen that, if using 2.7%
32 sulphur fuel, the input of OXS into the sea is trespassing the deposition from the 1% scenario already by 2020.
33 This is regardless of which scenario (4 or 5) is used. If all ships in the region south of Åland are using scrubbers,
34 and fuel with a sulphur content of 2.7%, the emission of sulphur oxides into the Baltic Sea is expected to be almost
35 three times the size in 2050, compared to if no scrubbers were used and fuel with sulphur content of 1.0% (Fig.
36 5b).

1 The deposition scenarios of sulphur from shipping, together with the historical data from Omstedt et al. (2015) are
2 shown in Fig 6. The deposition of sulphur from ship emissions in the Baltic Sea increased rapidly until the 1970s
3 and then more slowly until 2005 (e.g. Claremar et al., 2013). Applying scenario 2 or 3 the deposition becomes
4 significantly lower. The total deposition of sulphur in the Baltic Sea, from all emission sources, reached its
5 maximum in the second part of the 1900s. It has decreased steadily since then and the deposition of sulphur is
6 expected to continue to be low for the examined time period from present to 2050 (Fig. 7). The contribution of
7 deposition of oxidized sulphur from shipping is expected to increase somewhat from 2010 to 2050 in all basins of
8 the Baltic, but the levels will stay at low levels. The deposition of sulphur from all emission sources is predicted
9 to be rather invariable from 2010 to 2050, as given from RCP4.5.

10

11 The deposition in the whole Baltic Sea is presented in Table 3. The ship contribution to the total atmospheric OXS
12 deposition decreases, from 18% in 2011 to 5% in 2030 and 7% in 2050 (scen. 4). With scrubber, the contribution
13 adds up to more than 50%. In 2050 the atmospheric deposition has been reduced from 160 to 95 Mg yr⁻¹ but with
14 scrubber the input into the Baltic Sea is increased to 227 Mg yr⁻¹, an increase by 42% (scen. 4).

15

16 The deposition of nitrogen from ship emissions is expected to increase to all the basins in the Baltic Sea from
17 present to 2050 as we do not include any coming regulations on nitrogen (Fig. 8). The increase is due to increase
18 in traffic scenario. The total deposition of nitrogen in the Baltic Sea, from all emission sources, is expected to
19 increase in the Baltic Sea compared to current deposition level (Fig. 9). The increase of nitrogen deposition varies
20 significantly for the different basins and for the Kattegat basin the highest values of nitrogen deposition in the
21 1970s will be exceeded before year 2050. The contribution of deposition of oxidized nitrogen from shipping is
22 expected to become a more significant contributor to total deposition of oxidized nitrogen from 2010 to 2050 in
23 all basins of the Baltic Sea (Table 3). The OXN deposition is significantly lower than in J15. They used the
24 EC4MACS Interim Assessment (Amann et al. 2011) which indicates that the RCP4.5 has lower scenario on
25 nitrogen. That means that if using EC4MACS data, ship part of OXN deposition would be smaller, but total effect
26 be larger.

27

28 The deposition for OXN in the whole Baltic Sea is presented in Table 3. The ship contribution to total increases
29 for the atmospheric deposition, from 35% in 2011 to 60% in 2030 and 72% in 2050. In 2050 the atmospheric
30 deposition has been reduced from 77 to 88 Mg yr⁻¹, not counting for NECA.

31

32 We have, so far, not accounted for the long-term shift to TIER II and TIER III in NECA. A decision of a NECA
33 in Baltic Sea and North Sea was taken while preparing this paper. TIER II was introduced in 2011 and TIER III
34 will be introduced in 2021. In Table 4 estimates from J15 are shown and a reduction of emissions of 26% in Baltic
35 Sea and 29% in North Sea can be concluded in 2030, relative to without a NECA, i.e. to ships, mainly following
36 TIER II. We apply on our deposition a reducing factor due to both TIER II implementation and the NECA in 2021.
37 We assume that half of the fleet has implemented each regulation after 10 years, and completely after 30 years.
38 This yields power curves with exponent 1.7 as long as there are not more than three concurrent fleets. Further we
39 assume that TIER I was completely implemented in 2012 and that the implementation for TIER I is replaced by
40 TIER II until 2021 when TIER III takes over. Hence, in the period 2021-2031 when all TIER fleets are present,

1 the TIER II fleet remains constant at 50% until 2031 when TIER III reaches 50%. After that TIER II is the only
2 remainder to the TIER II fleet. The estimated fleet parts are presented in Fig. 10a. The ship emissions of NO_x in
3 the Baltic Sea is then scaled, using fleet weighted factors, with 85% for TIER II and 20% for TIER III, relative to
4 TIER I (J15). The resulting factors are shown in Fig. 10b. The deposition from shipping is then assumed to follow
5 the trends of emissions in the NECA in the basins, shown in Figs. 8, 9 (blue line). The deposition for OXN in the
6 whole Baltic Sea with the effect from NECA and TIER II is presented in Table 3. The ship contribution to total
7 first increases for the atmospheric deposition, from 35% in 2011 to 45% in 2030 and then decreases to 34% in
8 2050. In 2050 the atmospheric deposition has been reduced from 77 to 37 Mg yr⁻¹.

9
10 The deposition of OXS and OXN together acts as strong acids in the water. The result is an acidifying effect and
11 a pH decrease (Fig. 11). At pH 8, a proton input of 1 nmol m⁻² corresponds to a decrease in pH of 4·10⁻⁶ for a
12 mixed ocean surface layer of 10 m. For pH 8.2, this number is 7·10⁻⁶. The largest effect is seen in Kattegat where
13 ship traffic is high. In the worst case scenario, even with NECA, proton input is as high in 2050 as in 1970 to 1990.
14 In the larger basins in Baltic Proper, e.g. Eastern Gotland basin and Bornholm basin, the effect is smaller, whereas
15 in Gulf of Finland the proton input is almost as high as in 1970 to 1990. It is concluded that the introduction of
16 NECA really lowers the nitrogen input into Baltic Sea and the acidification is limited. However, using scrubbers,
17 the effect is limited to a few percent in proton input.

18
19 The difference in physics in EMEP model rv.4.4 and 4.8 causes different deposition. With the assumption that
20 rv.4.8 better represents the reality a correction was calculated for the Baltic Sea basins. The result is shown in Fig.
21 12 for OXS and OXN. It is seen that for OXS the difference is below 5%, and with a decreasing trend counting
22 from Kattegat to Bothnian Bay. The pattern for OXN is almost the opposite with the largest correction in the
23 northern parts. Also, the correction is higher, 10 to 30%. The impact on the future scenarios is discussed in next
24 section. The implication of this is that this has very small effect on sulphur, because the atmospheric deposition is
25 already low, especially compared to the exhaust from the scrubbers. The nitrogen is more important, although the
26 largest relative effects of the correction is in the Bothnian Bay where the deposition is smallest, just 50 mg m² in
27 2050. Therefore, and since the scenarios are connected to other uncertainties, a correction was not made.

30 **4.2 Present emissions and surface concentrations**

31 The spatial distribution of the emission from international shipping in the Baltic and North Sea in 2011 (from
32 EMEP model) is demonstrated in Fig 3a. The emission distribution (relative) is almost the same in 2013. The
33 highest emission levels of the pollutant are found near big ports and shipping lanes, especially in the area around
34 the English Channel and Denmark. Compared to ship emission 2011 there is a decrease in the inventory used for
35 the EMEP model (Table 4). There has been a decrease although not stepwise as if all ships were using 1% sulphur
36 in fuel, directly. This may be an effect of the interpolation as mentioned in section 2.3 (Fagerli et al., 2015), i.e. an
37 underestimation of the real ship emissions in 2012 and 2013. In Table 4 also the emissions used in J15 are shown.
38 There are sometimes large differences, possibly an effect of the resolution of data and Baltic Sea basin areas. The
39 largest deviation is for North Sea, but this area is not directly analysed in the present investigation.

1
2 The evaluation of the EMEP model concentrations (with rv.4.8) in 2013 is summarized in Figs. A1 and A2 and
3 Table A1 in the Appendix. The yearly averages of the measured and modelled concentrations of the pollutants
4 were rather consistent (Table A1). The EMEP model underestimates the concentrations of NO_x, SO₂ and PM at
5 both Utö and Vavihill, except for NO_x at Vavihill. The underestimations may be an effect of the underestimated
6 emissions mentioned above (Fagerli et al., 2015). The model has some difficulty to model the maximum values of
7 the observed data (Fig. A1), possibly an effect of the resolution.

8
9 The seasonal variability of modelled and measured concentrations at Vavihill and Utö in 2013 is shown as monthly
10 averages in Fig A2. There is an overall good agreement for most of the pollutants. However, NO₂ and SO₂ at Utö
11 deviated significantly for some time periods and PM₁₀ at Vavihill (Fig. A2, g). The seasonal changes are well
12 captured, but the variability is rather underestimated by the model. Bias, mentioned above, is also evident here.
13 An aspect of the evaluation is that observed data from point measurements were compared modelled data from
14 gridded boxes with the size of 50 km × 50 km. The regional resolution of the model, results in loss of variations
15 in the grid box and an average for the entire grid box is calculated, which in this study may have resulted in an
16 underestimation of the maximum values in shipping lanes and ports. This may also be a reason to why the model,
17 in general, had some difficulty to model the maximum values.

18
19 WHO guidelines for the annual average exposure for PM_{2.5} = 10 µgm⁻³; PM₁₀ = 20 µgm⁻³; NO₂ = 40 µgm⁻³; SO₂
20 = 20 µgm⁻³ (World Health Organization, 2006). EMEP model calculations by J15 have shown that in 2010 the
21 WHO guidelines of the annual averages for PM₁₀ and PM_{2.5} are exceeded in parts of the EMEP area. In the present
22 calculations for the year 2013 the concentrations of particulate matter still exceed the WHO guidelines in some
23 restricted parts of the Baltic Sea area (Fig. 13). Surface concentrations (near surface concentrations at 3 m) of SO₂
24 and NO₂ do not exceed WHO guidelines in 2011 to 2013 according to our EMEP calculations. It is also seen that
25 concentrations decreased between 2011 and 2013, as an effect of less ship emissions in the EMEP model input.
26 The PM_{2.5} concentration is in line with J15 but PM₁₀ is much higher in the present study over the North Sea,
27 probably because of different definition of the content. The explanation cannot be referred to sea salt, which is on
28 one order of magnitude smaller.

29
30 International shipping in the Baltic Sea and the North Sea contributes significantly to total surface concentration
31 of nitrogen oxides, sulphur dioxide and particular matter in 2009 to 2013. In some areas in the Baltic Sea region,
32 the contribution of nitric oxide, nitrogen dioxide and sulphur dioxide from international shipping represent up to
33 80% of total concentration of the pollutants from all emissions sources in 2013. For PM_{2.5}, the contribution from
34 shipping to total concentration was a maximum of around 20% and, for PM₁₀, 13%. The highest concentrations of
35 the pollutants are found near big ports and shipping lanes, where the shipping activities were most intense (Fig.
36 14). The highest concentrations of nitric oxide, nitrogen dioxide and sulphur dioxide are more clearly along the
37 shipping lanes, compared to PM_{2.5} and PM₁₀, in agreement with Aardenne et al. (2013). Variations in the results
38 between 2011 and 2013 are due to weather pattern and the decrease in ship emissions. Hence, locally the difference
39 between 2013 and 2011 can be up to 10 percentage units, both up and down, but less for PM, on the order of 2
40 percentage units. The actual annual mean concentration of PM_{2.5} from shipping is shown in Fig. 15. Comparing

1 to J15, the values and spatial distribution is overall good. However, there is a tendency of smearing out, expected
2 from the lower resolution in our study.

4 **4.3 Present Deposition**

5 The simulated (by rv.4.8) wet deposition, in 2013, from shipping in the Baltic Sea and North Sea reach over 60
6 mg(S)m^{-2} and 80 mg(N)m^{-2} in some of the areas in Europe (Fig. 3d and 17). The amount of wet deposition of the
7 pollutants is high in coastal areas, which may be due to enhanced precipitation by coastal, orographic and frictional
8 effects on the meteorology. This results in more deposited pollutants in countries with a long coastline. This is
9 consistent with the study of J15 where it was found that the deposition of nitrogen from shipping was high in the
10 seas and at coastlines. The large areas of OXN deposition over southern Norway, west coast of Sweden, and west
11 of Norway are both seen here and in J15. The dry deposition for the same year reach as maximum over 200
12 mg(S)m^{-2} and 65 mg(N)m^{-2} . The highest cumulative wet and dry depositions are found in areas close to some of
13 the shorelines in Europe and near big ports and shipping lanes (cf. Fig. 3). The total (wet and dry) cumulative
14 deposition of oxidized sulphur reached high values along the shipping lanes and its maximum values are found in
15 areas around the inlet to the English Channel. The maximum values of the total (wet and dry) cumulative deposition
16 of oxidized nitrogen are found at the Swedish west coast. Numbers and patterns of the N deposition are in line
17 with J15. This indicates that the resolution higher than $50 \times 50 \text{ km}^2$ is not of major importance for deposition of
18 the basin scale. Variations in the results between 2011 and 2013 are due to weather pattern and the decrease in
19 ship emissions. Hence, locally the difference between 2013 and 2011 could be up to 10 percentage units, both up
20 and down.

21
22 International shipping in the Baltic Sea and North Sea contributes significantly to the deposition of oxidized
23 sulphur and nitrogen, in 2009 to 2013. In 2013, the percentage contribution from the shipping to the total
24 cumulative wet deposition of sulphur from all emissions sources reaches 29% in some areas of the Baltic Sea
25 region and the contribution of dry deposition of sulphur is calculated to a maximum of 84% of total dry deposition
26 of sulphur in (Fig. 17). The percentage contribution of wet deposition of nitrogen reaches a maximum of 28% and
27 the contribution of dry deposition of nitrogen reached a maximum of 47%. Contribution of ship emissions to the
28 total (wet and dry) annual deposition of sulphur is as much as 56% in some areas and for nitrogen 29%. Deposition
29 pattern for the dry and wet deposition of oxidized sulphur and nitrogen differs slightly when wet deposition is
30 spread over a larger area than dry deposition. Dry deposition is more focused along ship routes. Dry deposition of
31 the pollutants caused by shipping represents, on the other hand, a higher percentage of total amounts of the
32 deposition than the wet deposition from shipping. The percentage contribution of dry deposition from shipping is
33 higher for oxidized sulphur than oxidized nitrogen.

35 **5 Discussion**

36 We have in this investigation focused on the impact from scrubbers in the future on sulphur deposition, its potential
37 acidification of the Baltic Sea, and in addition also included oxidized nitrogen. We have not taken into account

1 input from non-sea salt base cations, like calcium from cement industry, and ammonium from for instance
2 agriculture. Trends in those may alter acidification. For instance, calcium emissions have decreased, at least in the
3 90s and 2000s (e.g. Claremar et al. 2013). Similar deposition scenarios were used in Turner et al. (2017), but here
4 reduced NO_x emissions from the ship traffic is also evaluated. We here included estimations of the effect from
5 TIER II and NECA from 2030. The conclusion that scrubbers increase the ocean acidification still holds, but it is
6 decreased by less than 20 %, when including the effect from NECA. Without scrubber, the impact from NECA is
7 very large on reduced acidification. In other words, scrubbers offset the benefits of NECA. The introduction of
8 0.5% sulphur in fuel outside SECA is estimated to have a minor effect on the Baltic Sea deposition since the
9 atmospheric deposition is as low already now. The acid deposition from the scrubbers will also locally probably
10 be, even if it is horizontally mixed, a magnitude, or more, larger than the basin averages. In the worst case scenario,
11 at the basin scale, and assuming a mean mixing depth of 10 m of the surface water, the pH decrease in Kattegat
12 can be on the order $3 \cdot 10^{-4}$ per year (at pH 8.1). Locally, along shipping lanes, the pH decrease can be comparable
13 to CO₂ uptake (Fig. 12a).

14

15 This modelling study was based on international shipping emissions, which means that the contribution of
16 emissions from all shipping, including national, in the Baltic Sea and North Sea are somewhat higher than these
17 results show. In further work it would be of interest to include national emissions. To obtain more robust results,
18 national reported input data should be put under more control and a future study should as a suggestion also
19 examine how much impact it has on the result that several countries do not give complete reports of their annual
20 emissions, to reduce uncertainties in the model.

21

22 In this investigation we were using a mixture of modelling, and statistics, with all its uncertainties. We used
23 constant meteorology in the future scenario, but limited the uncertainties by using average of three meteorological
24 years (2009–2011). But in order to obtain more robust results a study over a longer period of time is required, in
25 the best case meteorology for every year. The resolution of the model, 50 x 50 km², compared to in J15 14 x 14
26 km², was shown to have a minor effect on basin scale studies. However, to see local effects at the coast, finer
27 resolution is needed. The validation to observations of coastal concentrations showed that the model performed
28 well, given the rather low resolution.

29

30 The new regulation of permitted weight percentage of sulphur in marine fuel was introduced in January 2015,
31 which makes it of interest to include 2015 and the following years in further studies, to analyse the outcome of the
32 new regulation. The 2015 0.1% limit was implemented in the scenarios but it remains to validate the compliance
33 and the traffic scenarios on the longer time scale. In further studies, it would also be of interest to include a
34 validation study of the deposition of the pollutants. Scenarios are based on assumptions on shipping activities as
35 well as fuel use and cleaning patterns. Alternative fuel or cleaning techniques might be developed giving
36 alternative scenarios.

37

38 To identify the dispersion of the different components of particulate matter from shipping it would be of interest
39 to model each component separately. Stricter regulations of sulphur content in maritime fuel and increased use of
40 other fuels will result in a new mixture of particulate matter from shipping. This ongoing change of composition

1 of the pollutants makes it of interest to understand the dispersion of each separate component. In further studies a
2 better resolution of the model is recommended to be used to examine the impact on local level. No seasonal
3 variations have been taken into account in this study. Results of the study of J15 demonstrate that emissions from
4 the international shipping vary to some extent over the year. The seasonal cycle of acidifying deposition is of
5 importance for the surface water, due to the biological cycle and stratification of the water, as seen in Omstedt et
6 al. (2015).

7 **6 Summary and Conclusions**

8 Model calculations using the chemical transport model EMEP show that the shipping in the Baltic Sea and North
9 Sea is an important source to high near-surface concentrations of nitric oxide, nitrogen dioxide, sulphur dioxide
10 and particulate matter, and deposition of oxidized nitrogen and sulphur in the Baltic Sea and North Sea area. The
11 highest concentrations of the pollutants were found near big ports and along shipping lanes. There, the international
12 shipping in the Baltic Sea and North Sea was responsible for up to 80% of near surface concentrations of nitric
13 oxide, nitrogen dioxide and sulphur dioxide in 2013. For PM_{2.5}, the contribution from shipping to total
14 concentration was up to 20% and, for PM₁₀, up to 13%. The. It can also be seen that the contribution from shipping
15 is of importance also over larger areas at sea and over land where many people are exposed. The percentage
16 contribution from international shipping to dry deposition of sulphur was calculated to a maximum of 84% and
17 contributions of dry deposition of nitrogen reached a maximum of 47% in 2013. Wet deposition from shipping
18 was spread over a larger area than dry deposition. Dry deposition of the pollutants caused by shipping represented
19 a higher percentage of total amounts of the deposition than the wet deposition.

20
21 Future scenarios of ship emissions and the use of open-loop scrubbers were combined with modelled deposition
22 from ships and other sources forming scenarios of acid deposition in the Baltic Sea basins. The impact of the
23 different scenarios differs slightly for the different basins in the Baltic Sea, with highest acidification in the
24 southern basins. The scrubbers focus the sulphur along the shipping lanes. Ship part of acidifying ocean deposition
25 increases for sulphur when including the scrubber water and for nitrogen oxides due to increasing ship traffic.
26 Direct acidification of ocean deposition from shipping increases for sulphur when including open-loop scrubbers.
27 The impact is even larger for the Baltic Sea as a whole, since almost all sulphur goes into the water and not to the
28 surrounding land areas. The estimates of the reduction in oxidized nitrogen deposition from introducing NECA in
29 2021, showed that there may be a large reduction of acidification. But in relation to the worst case scenario with
30 100% scrubbers in 2050, this effect is minor.

31
32 Considering the negative effects of the studied air pollutants and as the pollutants are a contributing factor of
33 several current challenges in the Baltic Sea and North Sea area, this study shows that continued analysis of the
34 maritime sector is required, in order to achieve sustainable shipping in the Baltic Sea and North Sea. For the marine
35 environment, a large-scale usage of open-loop scrubbers should be avoided, at least with the use of residual oil.

36
37 To conclude

- 38 • Open-loop scrubbers concentrate sulphur input along shipping lines, with enhanced potential for
39 acidification, even if the atmospheric deposition is estimated to be low.

- 1 • Acidification from a fleet with 100% scrubbers, using high sulphur content fuel, may reach the total
2 deposition levels along the shipping lanes from the 1970s to 1990s.
- 3 • Open-loop scrubbers will give a significant contribution to the marine environment, unless medium
4 sulphur content distillates are used.

5

6 **Acknowledgements**

7 This work is part of the Swedish Research Council Formas programme “Commercial shipping as a source of
8 acidification in the Baltic Sea (SHIpH)”, contract no. 2012-2120. The SHIpH group is acknowledged for valuable
9 discussion concerning the traffic and scrubber scenarios. It is also part of the “Baltic Earth – Earth System Sciences
10 for the Baltic Sea Region” program. The SHIpH group is gratefully acknowledged for valuable discussions on the
11 scenario definitions. Magnuz Engardt at SMHI is thanked for the MATCH model deposition output. EMEP/MSC-
12 W is acknowledged for the EMEP model code and input data. The EMEP model computations were performed
13 using resources provided by SNIC via the Uppsala Multidisciplinary Center for Advanced Computational Science
14 (UPPMAX) under projects snic2014-1-75 and snic2015-6-139.

1 **Figures and tables**

2 **Table 1.** International ship emission data for the different versions of the EMEP model used in this study

EMEP model version	Simulated years	International ship emission data
rv.4.4	2009-2011	ENTEC international shipping data (Jonson et al., 2009; ENTEC, 2010) and trends after 2000 are from IIASA (Cofala et al., 2007)
rv.4.8	2011-2013	Based on data developed by TNO in the EU Horizon 2020 project MACC III (Gauss et al., 2015)

3

4 **Table 2.** Future scenarios that differ with respect to the sulphur content of the fuel and scrubber usage

Scenario no.	Shipping not using wet scrubbers		Shipping using wet scrubbers	
	% of total	% sulphur in fuel	% of total	% sulphur in fuel
1	100	1.0	0	
2	100	0.5	0	
3	100	0.1	0	
4	50 by 2020	0.1	50 by 2020	2.7
5	0 by 2025	0.1	100 by 2025	2.7

5

6 **Table 3.** Total deposition of OXS and OXN in Baltic Sea Mg yr⁻¹.

	OXS		OXN	
	w/o scrubber (scen. 3)	w/ scrubber (scen. 4)	w/o NECA	w/ NECA
Tot dep 2011	160	160	77	77
Tot dep 2030	94	183	71	52
Tot dep 2050	95	227	88	37
From ships 2011 (%)	18	18	35	35
From ships 2030 (%)	5	51	60	45
From ships 2050 (%)	7	61	72	34

7
