1 **Abstract**

2 In this paper, we describe the development and application of a new spatially-explicit weathering
3 scheme within the University of Victoria Earth System Climate Model (UVic ESCM). We
4 integrated a dataset of modern-day lithology with a number of previously devised
5 parameterizations for weathering dependency on temperature, primary productivity, and runoff.
6 We tested the model with simulations of future carbon cycle perturbations, comparing a number
7 of emission scenarios and model versions with each other and with zero-dimensional equivalents
8 of each experiment. Overall, we found that our two-dimensional weathering model versions
9 were more efficient in restoring the carbon cycle to its pre-industrial state following the pulse
10 emissions than their zero-dimensional counterparts; however, in either case the effect of this
11 weathering negative feedback on the global carbon cycle was small on timescales of less than
12 1000 years. According to model results, the largest contribution to future changes in weathering
13 rates came from the expansion of tropical and mid-latitude vegetation in grid cells dominated by
14 weathering-vulnerable rock types, whereas changes in temperature and river runoff had a more
15 modest direct effect. Our results also confirmed that silicate weathering is the only mechanism
16 that can lead to a full recovery of the carbon cycle to pre-industrial levels on multi-millennial
17 timescales.

21

1 **1 Introduction**

2 **1.1 Rationale**

3 The weathering of carbonate and silicate rocks on land is a key process in the global carbon
4 cycle and, through its coupling with calcium carbonate deposition in the ocean, is the primary
5 sink of carbon on geologic timescales (Urey, 1952; Walker et al., 1981). The rate at which these
6 processes remove carbon from the Earth system is sensitive to changes in the environment,
7 notably temperature (Bernier, 1991), biological productivity (Lenton and Britton, 2006) and
8 perhaps more indirectly, river runoff (Walker and Kasting, 1992). This gives rise to a negative
9 feedback mechanism which regulates the global climate on multimillennial time scales.
10 However, its relevance over time frames of 10^4 years or shorter has of yet been left mostly
11 unexplored.

12 Here, we introduce a new model of rock weathering developed for use within the University of
13 Victoria Earth System Climate Model (UVic ESCM); this model incorporates a spatially explicit
14 interactive computation of weathering rates to close the global carbon cycle on multi-millennial
15 time scales. The model is based on a lithology-dependent calculation of steady-state weathering
16 fluxes, which are modulated by transient changes in environmental conditions akin to the 0-D
17 carbon cycle models already present in the literature (e.g. Meissner et al., 2012). We tested the
18 model with simulations of future climate changes following anthropogenic carbon emissions,
19 comparing the output to that of earlier weathering models, both 2-D (Colbourn et al., 2013) and
20 0-D (Lenton and Britton, 2006).

21

22 **1.2 The rock weathering cycle**

1 The chemical weathering of rocks is characterized by the cleavage of bonds of the mineral lattice
2 by water, often in the presence of a secondary weathering agent – hydronium or OH ions, low
3 molecular weight organic chelators, or carbonic acid (H₂CO₃; a product of carbon dioxide
4 dissolution in rainwater). Rock weathering products, including calcium and bicarbonate ions
5 (respectively the most abundant cation and anion in most river waters), can be carried away with
6 runoff to rivers and into the ocean. For example, calcium carbonate dissolution by carbonic acid
7 is given by (Archer et al., 1997):

9 The influx of dissolved inorganic carbon (henceforth DIC) and alkalinity to the ocean surface
10 layer is balanced by the precipitation and burial of biogenic calcium carbonate (CaCO₃) in the
11 marine sediments, and ocean alkalinity is a key factor in determining the carbonate compensation
12 depth (CCD), the depth below which the dissolution rate of calcium carbonate exceeds its
13 precipitation rate. In the long term this allows the ocean to maintain a remarkably stable
14 alkalinity, as any increases in ocean acidity (such as can be caused by a CO₂ invasion from the
15 atmosphere) can be neutralized by elevating the CCD, which dissolves carbonate sediments and
16 releases carbonate ions (CO₃²⁻) back into the ocean. This oceanic buffer factor, along with
17 carbonate dissolution on land (due to weathering), is the primary means through which ocean
18 alkalinity is restored, and is responsible for maintaining both atmospheric and oceanic pCO₂
19 close to equilibrium. In short, the weathering of calcium carbonate can accelerate the transfer of
20 CO₂ between the atmosphere and ocean, but does not contribute to a permanent return of carbon
21 to the geologic reservoir (Ridgwell and Zeebe, 2005; Sarmiento and Gruber, 2006).

22 A certain fraction of rock weathering reactions involve a weakening of chemical bonds in the
23 mineral lattice on contact with water whereby hydrogen ions replace positively charged cations

1 (mostly Ca^{2+} and Mg^{2+}) which are bounded to negatively charged ions, most particularly SiO_4
2 (silicate) structures. One of the most common examples is given by calcium silicate hydrolysis,
3 as described by following schematic reaction (Ebelmen, 1845; Urey, 1952):

5 This equation represents the weathering of any silicate mineral into silicic acid (which often
6 precipitates as amorphous silica SiO_2), and consumes one more molecule of CO_2 than carbonate
7 dissolution while sending the same amounts of calcium and bicarbonate ions to the ocean. The
8 combination of equation (2) with calcium carbonate precipitation (the reverse of equation 1)
9 shows how this results in a net removal of one molecule of CO_2 :

11 Weathering rates due to silicate hydrolysis tend to be considerably slower than from the
12 dissolution of carbonate minerals – it removes on average 0.28 to 0.30 Pg C per year (Amiotte
13 Suchet and Probst, 1995) – hence the effect of atmospheric CO_2 consumption by silicate
14 weathering only becomes a significant sink of carbon on geologic timescales (10^5 - 10^6 + years).
15 For the remainder of this article, dissolution of carbonates (on land) and hydrolysis of silicates
16 will be treated separately and referred to as carbonate and silicate weathering, respectively.

17 **1.3 A brief history of weathering in global carbon cycle models**

18 Variations in rock weathering rates have long been believed to hold a major role in regulating the
19 Earth's long-term climate, and early (non-spatially explicit) carbon cycle models were built to
20 investigate the importance of the weathering feedback mechanism on various events in Earth's
21 geological history. Walker, Hays and Kasting (1981), henceforth referred to as WHAK,
22 developed expressions relating silicate weathering rates to atmospheric pCO_2 (indirectly through

1 vegetation productivity) and temperature (including a weak dependency on runoff) and used
2 them to offer a solution to the faint young Sun paradox by providing a convenient mechanism for
3 a slow and steady decrease in atmospheric greenhouse gas concentrations. Berner, Lasaga and
4 Garrels (1983), henceforth referred to as BLAG, also linked the rate of atmospheric CO₂
5 consumption by silicate weathering to changes in surface air temperature, atmospheric partial
6 CO₂ pressure, and river runoff and offered this dependency as a possible explanation for the
7 general decreasing trend of atmospheric CO₂ levels on geologic timescales. Although these
8 models used rudimentary parameterizations derived from early general circulation models and
9 experimental data, they built a foundation for future long-term carbon cycle model studies.

10 Following BLAG, Berner (1991) built a geochemical cycle model, now called GEOCARB, in
11 which the long-term evolution of atmospheric carbon content would be driven by imbalances
12 between CO₂ outgassing by volcanic activity and the burial of carbonate sediments following the
13 weathering of silicate rocks. The latter was given a dependency on air temperature and
14 atmospheric CO₂, and it was used to solve a series of mass balance equations in order to
15 determine the inward and outward fluxes for the atmosphere-ocean, land, and mineralogical
16 carbon reservoirs. Subsequent versions were called GEOCARB II (Berner, 1994) and
17 GEOCARB III (Berner and Kothavala, 2001), and these further improved the weathering
18 parameterizations based on the latest observational data and GCM output. They were later
19 coupled with a model of atmospheric O₂ and ocean nutrients to create COPSE (Bergman et al.,
20 2004), a multi-element geochemical cycling model which introduces a feedback-based
21 interaction between biotic and abiotic elements of the Earth system. Most recent work on this
22 matter (Ridgwell and Hargreaves, 2007; Montenegro et al., 2007; Uchikawa and Zeebe, 2008;
23 Archer et al., 2009; Eby et al., 2009) has involved intermediate-complexity models, which are

1 usually limited in scope to 10^4 years or shorter. Hence the weathering feedback mechanism in
2 these studies is limited to the pH neutralization effect of carbonate weathering on the oceans
3 (which restores the lysocline to its original depth), and silicate weathering is either ignored
4 altogether or prescribed as a global constant average flux.

5 In a pioneering study, Walker and Kasting (1992) considered the impact of the rock cycle and
6 carbonate sediment dissolution in projections of future changes in the global carbon cycle. Their
7 model was built on the assumption that the dependency of carbonate and silicate weathering rates
8 to changes in the carbon cycle (aka. atmospheric CO_2 levels) was purely abiotic, which was in
9 line with the other geochemical cycling models of the time. Following on Walker and Kasting
10 (1992) as well as the recent innovations in COPSE, Lenton and Britton (2006) posited that
11 biological changes in the Earth system could further enhance the increase or decrease in rock
12 weathering rates, especially in the context of a rapidly warming world which would likely result
13 from unabated anthropogenic emissions. Their carbon cycle model included sophisticated biotic
14 and abiotic transports of carbon, introducing a box-model representation of carbonate and silicate
15 weathering processes in which weathering rates were directly dependent on plant productivity,
16 rather than on atmospheric CO_2 concentrations. This allowed them to investigate the role of land
17 use changes on the long-term recovery of atmospheric CO_2 ; in particular, they found that
18 vegetation-suppressing land use changes would force CO_2 levels to stabilize above preindustrial
19 levels on geologic timescales, thus indefinitely trapping some of the anthropogenic emissions in
20 the atmosphere.

21 **1.4 On spatially-explicit weathering models**

1 Few attempts have been made to explore the spatial variability of carbonate and silicate
2 weathering rates and how it may affect the global efficacy of the weathering negative feedback
3 mechanism. The GEM-CO₂ model (Amiotte Suchet and Probst, 1995) defined spatial variability
4 in terms of rock types, and using data for bicarbonate (HCO₃⁻) concentration and runoff collected
5 over various mono-lithologic drainage basins (Meybeck, 1987) to establish empirical linear
6 relationships between weathering flux and runoff for a series of major rock types, and calculated
7 the global distribution of CO₂ consumption by weathering based on the spatial heterogeneity of
8 those two factors alone. Their results showed a higher intensity of weathering in the Northern
9 Hemisphere (due to rock type) and in equatorial regions (due to runoff). They later refined the
10 global distribution of rock types by attributing one of six rock types to each land unit of a 1°×1°
11 grid (Amiotte Suchet et al., 2003); this distribution will be used as the basis for our spatially
12 explicit weathering scheme. Using the GEM-CO₂ model, carbonate rocks and shales were found
13 to both consume 40% of the total continental CO₂ uptake despite occupying a much smaller
14 fraction of land area, while sandstones and shield rocks contributed much lower than their
15 outcrop abundance. A similar rock type distribution was developed (Gibbs and Kump, 1994;
16 Bluth and Kump, 1994) (hence GKWM), using both an empirical linear coefficient and an
17 exponential factor to express weathering dependence on runoff for different rock types; the
18 results produced by their lithological distribution was found to be very similar to that of GEM-
19 CO₂, in terms of global weathering intensity and the consumption of atmospheric/soil CO₂.

20 Other instances of spatially-explicit weathering models include the GEOCLIM model
21 (Donnadieu et al., 2009), which uses 3-D GCM model results to prescribe changes in weathering
22 rates and investigate their impacts on a box-model ocean. It has been used to investigate the
23 climatic impacts of tectonic continental reorganization and weathering-vegetation interactions.

1 More recently, a spatially-explicit scheme was added to the GENIE model (Colbourn et al.,
2 2013), using lithological databases from the GEM-CO₂ and GKWM models, temperature
3 dependency from the GEOCARB models, NPP dependency as introduced by Lenton and Britton
4 (2006), and runoff dependency from GEM-CO₂. Although the paper focused mostly on
5 exploring the various model options, the authors were able to simulate the entirety of the climate
6 system recovery from a 5000 Pg C anthropogenic pulse at year 2000, showing that within 0.5-1
7 Myr the atmospheric CO₂ levels would return to pre-industrial levels.

8 **2 Methods**

9 **2.1 Climate model description**

10 In this study we used version 2.9 of the University of Victoria Earth System Climate Model
11 (henceforth UVic ESCM, or UVic model), which is an intermediate complexity coupled
12 atmosphere/ocean/sea-ice model with integrated land surface and vegetation schemes (Weaver et
13 al., 2001). Its main component is version 2.2 of the GFDL Modular Ocean Model (MOM), a
14 three-dimensional ocean general circulation model with 19 uneven vertical levels (Pacanowski,
15 1995), which is coupled to a vertically integrated energy-moisture balance atmosphere model
16 (Fanning and Weaver, 1996), a dynamic-thermodynamic sea-ice model (Bitz et al., 2001), a land
17 surface scheme and dynamic global vegetation model (Meissner et al., 2003), and a
18 sedimentation model (Archer, 1996). Land surface properties (surface temperature, soil moisture
19 content and temperature, and snow cover) and soil carbon content are computed with a single (1-
20 meter) layer version of the Meteorological Office Surface Exchange Scheme version 2 (MOSES-
21 2) (Cox et al., 1999), and terrestrial vegetation dynamics are handled by the Hadley Centre's
22 Top-down Representation of Interactive Foliage and Flora Including Dynamics (TRIFFID)

1 model (Cox, 2001). TRIFFID describes the state of the terrestrial biosphere in terms of soil
2 carbon content and vegetation distribution, which is expressed through the structure and
3 coverage of five plant functional types: broadleaf tree, needleleaf tree, C₃ grass, C₄ grass, and
4 shrub vegetation.

5 The UVic ESCM also includes a fully coupled global carbon cycle, which consists of inorganic
6 carbon chemistry and air-sea exchange of CO₂ (Ewen et al., 2004), and a Nutrient-
7 Phytoplankton-Zooplankton-Detritus (NPZD) module which calculates the contribution of the
8 biological pump to ocean biogeochemistry (Schartau and Oshlies, 2003; Schmittner et al., 2008).
9 Terrestrial carbon fluxes and reservoirs are described by Matthews et al. (2005), and coupled to
10 the global model by Meissner et al. (2003).

11 The model is driven in the short term by seasonal variations in solar insolation and wind fields
12 (Kalnay et al., 1996), and in the long-term by orbital parameter changes and a reconstruction of
13 atmospheric CO₂ content over the past 20 thousand years (Indermühle et al., 1999). The spatial
14 coverage and height of continental ice sheets is prescribed every 1000 years using data from the
15 model ICE-5G (Peltier, 2004); thus these ice sheet configurations also serve to drive climate
16 changes during glacial periods. The land-sea configuration used in all sub-components operates
17 in a global spatial domain with a spherical grid resolution of 3.6° (zonal) by 1.8° (meridional),
18 which is comparable to most coupled coarse-resolution AOGCMs.

19 **2.2 Weathering model description**

20 Terrestrial weathering in the UVic model is parameterized as a land-to-ocean flux of dissolved
21 inorganic carbon (F_{DIC}) and alkalinity (F_{ALK}, with F_{ALK} = 2F_{DIC}) via river discharge. In the
22 standard version of the model, the incoming flux of carbon to the ocean as weathering is set to

1 equal the net burial rate of CaCO_3 in order to balance the long-term carbon and alkalinity
2 budgets in the ocean; the initial, steady-state value is typically held constant throughout the
3 transient model runs. This effectively suppresses the long-term negative feedback mechanism by
4 preventing the weathering rate from adapting to changes in environmental factors such as
5 temperature and atmospheric CO_2 concentration. Meissner et al. (2012) replaced the standard
6 parameterization of weathering in the UVic model with a number of adaptations from previous
7 carbon-cycle box models in order to investigate the role of rock weathering as a carbon sink for
8 anthropogenic carbon emissions. They found that the long-term climate response to various
9 emission scenarios depends almost exclusively on the total amount of CO_2 released regardless of
10 the rate at which it is being emitted, and carbon uptake through an increase in terrestrial
11 weathering has a significant effect on the climate system. There were, however, some
12 differences between the various weathering schemes concerning the rate of carbon removal.

13 In this section we describe a spatially explicit weathering scheme developed for use within the
14 UVic ESCM. Steady-state carbonate and silicate weathering rates are calculated for each land
15 grid cell based on the local rock type (Sect. 2.2.1) and runoff (Sect. 2.2.2). In transient model
16 runs, these values are modulated by changes in temperature, atmospheric CO_2 concentrations or
17 vegetation productivity, and runoff (Sect. 2.2.3), which are updated on each time step based on
18 model output. Changes in carbonate and silicate weathering rates are returned to the model in
19 the form of a riverine flux of carbon and alkalinity (Sect. 2.2.4), which is routed to the ocean.

20 *2.2.1 Worldwide distribution of rock types*

21 The two-dimensionality of the weathering model is rooted in the uneven distribution of rock
22 types across the world. Thus, regions with more active lithologies yield higher weathering rates

1 under similar climate conditions, and these are more sensitive to changes in climate controls than
2 regions predominantly covered by weathering-resistant lithologies (igneous and metamorphic
3 rocks, basalts and granites). Whereas the worldwide distribution of continental rock lithology is
4 well known, there is only limited knowledge of the impact of different rock types on the amounts
5 of riverine exports, therefore any estimation of weathering rates based on local lithological
6 composition is subject to some discrepancy.

7 In this study we used the lithological distribution paradigm first introduced in GEM-CO₂, and
8 later published by Amiotte Suchet et al. (2003). The flux of atmospheric/soil CO₂ from
9 chemical weathering on each continental grid cell was given an empirical linear relationship to
10 runoff (see Sec. 2.2.2) depending on its assigned predominant lithological category. Rock types,
11 from having the smallest to largest impact on weathering, are classified as follows: plutonic and
12 metamorphic (shield) rocks, sands and sandstones, extrusive igneous (acid volcanic) rocks,
13 basalts, shales and evaporites, and carbonate rocks, the latter of which designs a loose group of
14 predominantly carbonate-based rocks (for example, limestones). Sedimentary rocks (carbonates,
15 shales, sandstones) contain significant amounts of carbonate rocks, and thus do not consume
16 atmospheric CO₂ as efficiently as other rock types, despite sending a higher riverine flux of
17 weathering products. In the other rock types, the prevalence of carbonate minerals is too
18 variable and difficult to estimate, hence they are assumed to contain only silicate-weathered
19 minerals.

20 The adaptation of the rock type distribution map to the UVic model is shown in Figure 1. The
21 spatial resolution of the UVic model (3.6°×1.8°) is about 6.5 times coarser than that of the
22 original database (1°×1°) hence the adapted rock distribution paradigm was defined according to
23 the partitioning of rock types within the area contained by each UVic model grid cell. The

1 resulting runoff multiplier and carbonate to silicate fractionation therefore becomes a weighted
2 spatial average of all of rock type multipliers in Table 1.

3 2.2.2 Calculating the steady-state weathering rate

4 The reference weathering rate is calculated for each individual grid cell based on local steady-
5 state runoff R_0 (Figure 2a) and rock type composition. Following Amiotte Suchet and Probst
6 (1995), the local riverine fluxes of bicarbonate ions from carbonate (f_{Ca}) and silicate (f_{Si})
7 weathering are computed as:

$$f_{Ca} = R_0 \sum_i frac_i k_i \alpha_i \quad (5)$$

$$f_{Si} = R_0 \sum_i frac_i k_i (1 - \alpha_i) \quad (6)$$

8 where $frac_i$ is the fraction of rock type i present in the grid cell, k_i is the rock type specific
9 weathering rate multiplier, and α_i is the fraction of rock type given to weather as carbonate
10 rocks. The different rock types and their weathering parameters are shown in Table 1. The
11 weathering rate multipliers (k_i) were derived from the data by Amiotte Suchet et al. (2003) and
12 the fractionation of rock types between carbonate and silicate rocks is adapted from the work of
13 Gibbs et al. (1999), following the interpretation of Colbourn et al. (2013). The reasoning behind
14 our not including temperature or NPP in the spinup is that the steady-state weathering rates,
15 which depend on the boundary conditions relevant to preindustrial conditions (including
16 atmospheric CO_2 concentrations), must necessarily reflect the steady-state climate and
17 environment.

18 The resulting steady-state carbonate and silicate weathering rates at pre-industrial (1800AD)
19 conditions are shown in Figure 2b. There is a noticeable concentration of $CaCO_3$ weathering in

1 areas of high runoff with bedrock composed predominantly of carbonate rocks (for example,
2 Southeast Asia), whereas CaSiO_3 weathering is spread more evenly across the world. It is
3 noteworthy that the Amazon basin features by far the highest runoff yet produces unremarkable
4 weathering rates (compared to other tropical areas) due to the prevalence of the weathering-
5 resistant shield rocks. The same observation can be used to explain the low weathering rates in
6 central Africa. This weathering distribution compares reasonably well with the CO_2
7 consumption distribution found by Amiotte Suchet and Probst (1995), but it doesn't reproduce
8 the large values at northern high latitudes (especially in northern Asia) that can be found using
9 the GEM- CO_2 model. The distribution of bicarbonate fluxes of Gibbs and Kump (1994) displays
10 a somewhat lower equator-to-pole gradient in weathering rates, and suggests an area of high
11 weathering in the southeast USA which is not reproduced with our model, mainly on account of
12 low runoff in the region. These discrepancies are likely due to precipitation bias in the UVic
13 ESCM. However, both models appear to agree with our finding that southeastern Asia is the
14 region with the highest regional weathering intensity. Globally, the 2-D weathering scheme
15 sends a DIC flux of 0.166 Pg C/y into the ocean, which is approximately 15% more than the 0-D
16 model output (0.145 Pg C/yr) (Meissner et al. 2012), and on par with previous estimations of
17 pre-industrial global weathering intensity (see for example, Moon et al. 2014).

18 2.2.3 *Modulation of weathering rate*

19 In transient model simulations, the carbonate and silicate weathering rate for each grid cell is
20 modulated by changes in local environmental conditions. They were made dependent on surface
21 air temperature, atmospheric carbon dioxide content, and runoff in a similar manner to previous
22 carbon cycling models. Following Lenton and Britton (2006), we have included the option of

1 replacing the dependency on CO₂ concentration by vegetation productivity, which more directly
2 accounts for the impact of biological factors on weathering intensity.

3 Temperature is a known controller of weathering intensity as higher temperatures increase the
4 kinetic energy of molecules, facilitating the atomic encounters which lead to the chemical
5 dissociation of minerals. Although it is impossible to derive a relationship between temperature
6 and weathering rates from first principles, laboratory and field studies have correlated the
7 concentration of bicarbonate ions in a solution to water temperature in order to develop an
8 empirical formulation. For carbonate weathering, we used the results of Harmon et al. (1975),
9 who compared the groundwater temperature and bicarbonate ion concentration of several North
10 American watershed to come up with the following empirical relationship:

$$g_{Ca}(SAT) = 1 + 0.049(SAT - SAT_0) \quad (7)$$

11 where SAT and SAT_0 are the transient and steady-state surface air temperature, respectively. For
12 silicate weathering, we used a version of the Arrhenius rate law of Brady (1991) which was
13 adapted into the RokGeM by Colbourn et al. (2013):

$$g_{Si}(SAT) = e^{0.09(SAT - SAT_0)} \quad (8)$$

14 Here, the constant of 0.09 inside the exponential expression was obtained using an activation
15 energy of 63 kJ mol⁻¹ for silicate weathering and a global initial temperature of 288K (global
16 average pre-industrial temperature). The activation energy is poorly constrained, but has been
17 shown to have little effect on the long-term consumption of atmospheric CO₂.

18 The productivity dependence of weathering serves to illustrate the biological and soil-
19 enhancement factors which control weathering intensity, with vegetation net primary
20 productivity a suitable proxy for biological activity in an area. Lenton and Britton (2006)

1 introduced a simple linear dependence of weathering on productivity based on the steady-state
 2 proportion of global productivity to global weathering flux:

$$g(NPP) = \frac{NPP}{NPP_0} \quad (9)$$

3 where NPP and NPP_0 are the transient and steady state net primary production, respectively,
 4 taken explicitly from the output of the coupled land surface scheme MOSES-2 and vegetation
 5 module TRIFFID. This formulation works reasonably well in 0-D models with globally-
 6 summed values of productivity and weathering rate; however, some problems arise when trying
 7 to use it in a spatially-explicit model due to its inherent assumption that productivity and
 8 weathering intensity are directly related at steady state. A good example of this would be at the
 9 continental margins of predominantly ice-covered continental landmasses (Greenland,
 10 Antarctica) where some of the land may be ice-free, but too cold to support any vegetation.
 11 However, the presence of nearby ice sheets generates a meltwater runoff flux which greatly
 12 enhances weathering, in spite of the lack of vegetation. Therefore, any expansion of vegetation
 13 in this area, however small (which is not unrealistic given the extreme warming scenarios
 14 examined here), would result in an unreasonable increase in weathering. In order to rectify this
 15 situation, we have introduced a modified version of equation 9 which calculates the increase in
 16 local weathering rate when NPP is greater than its steady-state value:

$$g(NPP) = \begin{cases} NPP/NPP_0, & NPP < NPP_0 \\ \left(1 + \frac{(NPP - NPP_0)/NPP_{0,global}}{f_0/f_{0,global}} \right), & NPP \geq NPP_0 \end{cases} \quad (10)$$

17 where $f_0 = f_{Ca} + f_{Si}$ and the “*global*” indices indicate the globally-summed value of that
 18 variable. The right-hand term in the brackets is a compensation term, which modifies the

1 increase in weathering based on the relative contribution of the grid cell to the global
2 productivity compared with its contribution to the global weathering flux. This results in a
3 redistribution of NPP-induced changes in weathering without changing the globally-summed
4 increase in weathering intensity (this is true only in the absence of other controlling factors, such
5 as temperature). Note that the parameterization is unchanged from equation (9) whenever NPP
6 is lower than its initial value, mostly to avoid computing negative values of $g(\text{NPP})$. This has a
7 relatively benign impact on the global result, as the values calculated from equation (10) only
8 differ significantly from those of equation (9) when NPP is much greater than NPP_0 .

9 As an alternative to productivity dependence, we also included the option to parameterize
10 weathering as a function of atmospheric CO_2 content, following the approach used in the
11 GEOCARB II model of Berner (1994):

$$g(\text{CO}_2) = \left(\frac{2 \frac{p\text{CO}_2}{p\text{CO}_{2,0}}}{1 + \frac{p\text{CO}_2}{p\text{CO}_{2,0}}} \right)^{0.4} \quad (11)$$

12 where $p\text{CO}_2$ and $p\text{CO}_{2,0}$ are the transient and steady-state atmospheric concentration of CO_2 ,
13 respectively. This relationship has long been used to estimate the fertilizing effect of CO_2 on
14 land plants, and thus becomes here an indirect parameterization of the biological enhancement of
15 weathering. It can be used *in lieu* of equations 9 and 10 as a model option.

16 Runoff is the most widely used factor of weathering intensity as it constitutes a good proxy for
17 the strength of the water cycle in an area. One may consider the fact that high runoff
18 environments tend to be associated with intense weather activity (the rainforests, for example),
19 and also that stagnant waters quickly become saturated, thus limiting the efficiency of

1 weathering. Given that we already include runoff in the calculation of steady-state weathering,
2 the transient runoff dependency is a simple adjustment following *Berner* [1994]:

$$g_{Ca}(R) = \frac{R}{R_0} \quad (12)$$

$$g_{Si}(R) = \left(\frac{R}{R_0}\right)^{0.65} \quad (13)$$

3 where R and R_0 are the transient and steady-state river runoff, respectively, which are also taken
4 explicitly from the output of the land surface scheme MOSES-2. The difference between the
5 formulations for carbonate and silicate weathering is an empirical correction based on the
6 assumption that bicarbonates from the weathering of silicate rocks are more diluted in rivers than
7 for carbonate weathering. The value of 0.65 in equation (13) was taken from *Berner* (1994);
8 although the value itself has a large margin of error, it has been shown to have only a modest
9 effect on the overall efficiency of the weathering feedback mechanism.

10 To summarize, we have developed a two-dimensional weathering scheme whereby the steady-
11 state values of carbonate and silicate weathering fluxes (see Sect. 2.2.2) are modulated by
12 changes in temperature, vegetation productivity (alternatively: atmospheric CO₂ concentration),
13 and runoff. Thus the complete weathering parameterizations take the form:

$$F_{Ca} = f_{Ca} \cdot g_{Ca}(SAT) \cdot g(NPP) \cdot g_{Ca}(R) \quad (14)$$

$$F_{Si} = f_{Si} \cdot g_{Si}(SAT) \cdot g(NPP) \cdot g_{Si}(R) \quad (15)$$

14 Weathering is calculated in each individual land grid cell, and routed to the coastal ocean as
15 fluxes of alkalinity and dissolved inorganic carbon. The UVic model divides the continental
16 land area into a set of pre-determined drainage basins, and the riverine fluxes into the oceans are
17 spread evenly across the continental margins (land grid cells adjacent to ocean) for each drainage

1 basin (see Weaver et al., 2001). The input of weathering products is implemented into the model
2 as riverine fluxes; however, they are immediately redistributed evenly across the ocean surface
3 layer.

4 2.2.4 *Effects of weathering on ocean biogeochemistry*

5 In the UVic ESCM, weathering does not have a direct impact on atmospheric or land surface
6 carbon; its effects are prescribed through the riverine exports of weathering products which are
7 sent to the ocean and modify its chemical composition. The chemical weathering processes are
8 described by equations 1 (carbonate) and 2 (silicate), both resulting in a flux of two moles of
9 bicarbonate ions (HCO_3^-). The flux of dissolved inorganic carbon (F_{DIC}) is counterbalanced by
10 the consumption of atmospheric carbon dioxide during the weathering reactions, leaving a net
11 DIC flux of one mole for carbonate weathering, and none for silicate weathering; a constant term
12 was also added to represent the contribution of volcanic outgassing to global carbon emissions
13 (which is not included in the UVic model):

$$F_{DIC} = F_{Ca} + F_{volc} \quad (16)$$

14 Given that, in the absence of external forcings, the CO_2 consumption by silicate weathering is
15 meant to counter the intake of carbon from the geologic reservoir from volcanic eruptions, we set
16 the constant term F_{volc} to equal the steady-state flux of silicate weathering ($F_{volc} = F_{Si,0}$).
17 Meanwhile, the net flux of alkalinity (F_{ALK}) remains equal to the flux of bicarbonate ions. The
18 above discussion is summarized in the following set of equations, which describes the
19 partitioning of carbonate weathering and silicate weathering fluxes into dissolved inorganic
20 carbon and alkalinity fluxes, which are then globally summed and fed to the ocean
21 biogeochemistry module:

$$F_{DIC} = F_{Ca} + F_{Si,0} \quad (17)$$

$$F_{ALK} = 2F_{Ca} + 2F_{Si} \quad (18)$$

1 Note that our choice of F_{volc} effectively equilibrates ocean biogeochemistry during equilibrium
2 runs ($F_{ALK,0} = 2F_{DIC,0}$). The values calculated here represent net fluxes over the entire surficial
3 (atmosphere-land-ocean) reservoir, and in particular the simplification for the net flux of DIC is
4 based on the assumption that the consumption of CO_2 from the atmosphere is immediately
5 balanced by an equivalent outgassing of carbon from the ocean. This would be true in general,
6 given that the timescale of the weathering negative feedback mechanism far exceeds that of
7 atmosphere-ocean mixing; however in the timescales considered here (10^3 - 10^4 yrs) there would
8 be some delay between the consumption of CO_2 from the atmosphere and the release of CO_2 in
9 the ocean following $CaCO_3$ burial – this delay comes from the average time it takes for the
10 calcium and carbonate ions in the seawater to precipitate again as calcium carbonate, which
11 releases a molecule of carbon dioxide. This delay would not significantly alter the impact of
12 weathering on atmospheric geochemistry, but could reduce by as much as 10% the rate at which
13 alkalinity increases in the ocean (Colbourn et al., 2013).

14 **2.3 Steady-state weathering and description of transient model simulations**

15 Pre-industrial steady-state weathering was obtained by integrating the model for over 20,000
16 years under year 1800 boundary conditions, using rock type dependency and distribution as
17 detailed in sections 3.1.1 and 3.1.2. Land-to-ocean weathering fluxes stabilized in less than 10^3
18 years, on account of runoff being mostly computed from atmospheric output. However, the
19 fixing of deep ocean alkalinity and dissolved inorganic carbon (DIC) content from transient to
20 steady-state values (along with the non-constant weathering scheme) would have required as
21 much as 10^5 model years – an impossibly long simulation time given the level of complexity of

1 the UVic model. Hence we extracted the model steady state after 10^4 years, but kept the
2 background steady-state run ongoing concomitantly with the transient model simulations in order
3 to correct the output of the latter based on changes in the former; at the time of extraction, the
4 ocean DIC and alkalinity content were about 7-8% away from their equilibrium value. Each
5 transient simulation was forced with the historical natural and anthropogenic carbon emission for
6 200 years; at year 2000 an additional 5000 Pg C were emitted over one year (unless otherwise
7 indicated), and carbon emissions were set to zero thereafter. All simulations were carried out for
8 a period of ten millennia, ending at year 12,000.

9 A total of eight model versions were integrated to year 12,000, which we classified into three
10 groups of experiments (see Table 2 for a description of all experiments). Group A (Section 3.1)
11 experiments investigate the impact of the intensity and span of the prescribed carbon emissions.
12 Simulation A0 is the basic emission scenario outlined in the above paragraph, and thus served as
13 the main control run for this paper. Simulation A1 is similar but used a more conservative
14 estimate of 1000 Pg C for future anthropogenic emissions. Finally, simulation A2 extended the
15 carbon emission total of 5000 Pg over a much longer period: emissions were increased linearly
16 until reaching double the current (year 2000) carbon emissions; the remaining carbon emissions
17 were then distributed evenly during the period from 2050 to 3000, then set to zero thereafter.
18 Although distributed over a longer period, the total carbon emissions remained unchanged from
19 our control run A0.

20 Group B experiments (Sect. 3.2) compare the various model representations of the biological
21 enhancement factor. In simulation B1, we replaced the NPP dependence term $g(NPP)$ in
22 equations 14 and 15 with $g(CO_2)$ from equation 11 on all grid cells. Although carbon dioxide
23 concentrations in the atmosphere are known to vary slightly across the surface of the Earth, in

1 the UVic model pCO_2 is a global term with no defined spatial variability. This effectively
2 removes the two-dimensionality of the biological feedback term, leaving temperature as the sole
3 spatially-explicit variable. Runoff does not vary much unless there are major changes in
4 hydrology or ice sheet distribution, neither of which were considered in our simulations. A
5 further simplification was made in simulation B2 by removing the biological enhancement factor
6 altogether and incorporating a parameterization that is only based on the temperature-dependent
7 part of our spatially-explicit scheme.

8 Group C experiments (Sect. 4.3) compare the relative importance of carbonate and silicate
9 weathering through their impacts on riverine fluxes of alkalinity and DIC. In simulation C1, we
10 eliminated the silicate weathering feedback ($F_{Si} = f_{Si}$), leaving only the carbonate weathering
11 part of the parameterization. Likewise, in simulation C2, the carbonate weathering feedback was
12 negated ($F_{Ca} = f_{Ca}$), isolating the impact of the silicate weathering feedback. Finally, in model
13 version C3 we eliminated both carbonate and silicate weathering feedbacks to maintain constant
14 weathering fluxes (at steady-state values) throughout the simulation. This last model version
15 effectively simulates the carbon sequestration potential of the oceans in the absence of the
16 weathering feedback mechanism.

17 For each of the model versions outlined above (with the exception of C1 and C2), an identical
18 setup was used with a zero-dimensional version of the weathering model whereby weathering
19 rates were calculated based on global, rather than local changes in the control parameters
20 (temperature, NPP, runoff); these 0-D model versions are identified in the figures using the “*”
21 notation (for example, “A0*” refers to the zero-dimensional version of simulation A0). The code
22 for these 0-D model versions was developed in an earlier study of terrestrial weathering changes
23 with the UVic model (Meissner et al., 2012).

1 **3 Results**

2 **3.1 Group A results**

3 The time series of CO₂ concentration in the atmosphere as well as weathering fluxes of carbon
4 and alkalinity are shown in Figure 3a for each of the pulse (group A) scenarios (solid lines), and
5 compared with results from similar scenarios using the 0-D version of the model (dotted lines).
6 For all simulations, the 2-D model was always more efficient in removing CO₂ from the
7 atmosphere than its 0-D counterpart. This can be partially explained by the initial global total
8 weathering being slightly higher in the 2-D model (see Section 2.2.2); however, this cannot
9 account for alkalinity weathering increasing nearly three times as much in the 2-D model as it
10 does in the 0-D version (interestingly, 0-D weathering rates seem to be slightly higher than 2-D
11 values for scenario A1). Instead, we propose that this is a natural consequence of using a two-
12 dimensional approach. Temperature, productivity, and runoff are closely related, as all three are
13 positively affected by the increase in atmospheric CO₂: temperature from the greenhouse effect,
14 NPP through the CO₂ fertilization of plants, and runoff as a result of both a temperature (hence
15 precipitation) increase and the CO₂-induced increase in plant water-use efficiency. Vegetation
16 productivity also reacts positively to increases in temperature in extratropical regions, although
17 this effect could be overcompensated for by an opposite reaction in tropical regions, where
18 temperatures exceed the threshold for optimized plant growth (Matthews et al., 2005; Matthews
19 et al., 2007). This means that areas which see a large increase in one variable will more often
20 than not see equally large increases in one or both of the other variables, further enhancing the
21 local increase in weathering rates. A zero-dimensional model would not be able to create this
22 effect because it uses globally summed or averaged variables. This is especially important with

1 regards to temperature, as the global average would be dominated by oceanic SAT changes,
2 which tend to be smaller than continental SAT changes.

3 Scenario A2, when compared to A0, suggests that the ability of the Earth system to recover from
4 anthropogenic emissions is essentially independent of the rate at which the emissions occur.
5 Atmospheric CO₂ concentrations recovered more slowly in the gradual emissions scenario at first
6 since weathering fluxes were not increased as much, but the gap between the two curves
7 gradually narrowed after A2 emissions ended at year 3000. We found a modest difference of 13
8 ppm in atmospheric CO₂ concentration between A0 and A2 at year 12,000 (8 ppm when
9 comparing both 0-D runs), which is comparable if not a little larger than the difference between
10 the pulse and IPCC A2 simulations in Meissner et al. (2012), in which a 5000 Pg C pulse was
11 spread over 300 years. Given that the longer the carbon emissions are spread out over time, the
12 longer it takes for atmospheric CO₂ levels to catch up to a pulse scenario, we can surmise that
13 pulse scenarios would overestimate the ability of the weathering feedback mechanism to remove
14 carbon from the atmosphere in the next several millennia, unless a way is found to mitigate
15 anthropogenic emissions within the next century.

16 Time series of various carbon reservoirs for Group A scenarios are shown in Figure 3b. The
17 ocean reservoir content at year 12,000 was nearly identical for scenarios A0 and A2, indicating
18 that the ocean was even more indifferent to the rate of carbon emissions than the atmosphere.
19 Zero-dimensional model ocean carbon exceeded the 2-D output at around year 8500 for
20 scenarios A0 and A2, due to the fact that there was more carbon remaining in the atmosphere-
21 ocean system. It is interesting that the land and sediment carbon reservoirs behaved differently
22 from other reservoirs in cases of large or extended carbon emissions. The latter (and associated
23 temperature anomalies) in A0 and A2 appeared to have a counterproductive effect on land

1 carbon content, which was not seen under the more modest temperature increase of simulation
2 A1. If anything, this results points out the inability of the land reservoir to store any significant
3 amount of excess carbon from the atmosphere on millennial timescales. Finally, the sediment
4 carbon curve also behaved somewhat counterintuitively, as all three 2-D pulse scenarios
5 produced a comparable increase of sediment carbon content, regardless of emission rate or
6 amount of carbon released. For the 0-D model versions, total CaCO_3 sediment budget increased
7 more rapidly for scenario A1 despite lower amounts of carbon emitted. These results arise
8 because the solubility of calcium carbonate in seawater, which determines its precipitation rate,
9 depends on a delicate balance which involves ocean temperature (increasing solubility at higher
10 solvent temperatures), alkalinity, and calcite concentration. Oceans in scenario A1 contained
11 less CO_2 and CaCO_3 , but were also cooler than in A0 and A2, which may explain why the total
12 accumulation of CaCO_3 sediments was comparable between all three scenarios. However, even
13 though the buried mass of CaCO_3 was constantly increasing in all scenarios, the pore layer mass
14 depicts a more accurate version of what happens with ocean biogeochemistry during that time.
15 After year 3000, the pore layer mass in all scenarios become negative, indicating that the rate of
16 dissolution of carbonates exceeds the burial rate. This is to be expected and represents a
17 shoaling of the lysocline in response to a sudden increase in oceanic carbon content as ocean
18 pCO_2 tries to reach equilibrium with atmospheric pCO_2 .

19 Global changes in surface air temperature, vegetation NPP, and surface runoff are shown in
20 Figure 4 at various times during the 10,000 year simulation. As seen in Figure 4a, the most
21 significant changes in temperature mostly occurred poleward of 60 degrees of latitude; however,
22 there were also increases in many tropical regions. These results are to be expected given the
23 static nature of wind fields in the UVic model, which prevent a reorganization of atmospheric

1 circulation and thus trap the warm anomalies in the tropics. Figure 4a (see also Figure 3c) also
2 reveals that the cooling effects of carbon sequestration were not felt until well after year 3000,
3 despite atmospheric CO₂ concentrations being decreased by nearly 1000 ppm between years
4 2000 and 3000; this is simply due to the thermal inertia of the ocean (Matthews and Caldeira,
5 2008). By year 12,000, temperature anomalies across the globe became fairly uniform, with
6 every area averaging 1-2°C warmer than pre-industrial state.

7 Changes in vegetation net primary productivity are shown in Figure 4b. Most of the world saw
8 an increase in vegetation activity from the direct effect of CO₂ fertilization, with the exception of
9 desert areas which remained the same (Africa, Asia) or become more arid (Australia). Changes
10 in NPP also correlated well with changes in river runoff (Figure 4c); this is mainly a
11 consequence of the effect of increased CO₂ concentrations on plants, which optimises vegetation
12 water-use efficiency, leading to an increase in soil moisture and therefore runoff (Nugent and
13 Matthews, 2012; Cao et al., 2010). The very large NPP increase in Indonesia around year 3000
14 was likely caused by the replacement of rainforest by the much more productive C4 grasses, and
15 further enhanced by a 1000-year legacy of high CO₂ fertilization. The validity of this outcome,
16 and that of the 9°C surface air temperature increase over the region which is the apparent cause
17 of this shift in vegetation regime, can be put into doubt. It is possible that the tropical forests
18 would attempt to resist the extreme warming through increased evapotranspiration rates, for
19 example, to avoid being exposed to temperatures that would be threatening to their survival. It is
20 also possible that due to the short time scale of the perturbation (a few thousand years), plant
21 species would not have time to adapt to the rapid warming and would indeed die off and be
22 replaced by a better suited plant functional type – this could help explain the extremely high
23 temperature increase over the region. Other tropical forests do not, in fact, show this behavior.

1 The Amazonian forest, in particular, remains remarkably stable over the same time period, with
2 much smaller changes in NPP and a smaller increase in surface air temperature over the region as
3 well.

4 The resulting impacts of these changes in temperature, vegetation productivity, and runoff on
5 CaCO_3 and CaSiO_3 weathering are shown in Figure 5. A qualitative visual assessment of the
6 results revealed that changes in weathering appeared to be more strongly correlated to changes in
7 NPP, and to a lesser extent, runoff. The influence of rock type distribution was also noticeable,
8 especially on the carbonate/silicate weathering partitioning, while temperature had an overall
9 modest impact. Most areas saw a moderate to high increase in both weathering types, with the
10 exception of arid areas (deserts and ice caps) which experienced a minor decrease in weathering.
11 The most significant change occurred in central western Asia (Kazakhstan), where a favorable
12 combination of low initial NPP and a high enough initial weathering rate made it possible for
13 weathering values to become excessively high when the increase in temperature lead to a drastic
14 (and very temporary) increase in vegetation productivity during the third millennium CE. This
15 anomaly all but disappeared in later snapshots of the simulation, once global temperatures were
16 no longer warm enough to sustain such high levels of vegetation productivity. Indonesia also
17 saw a large increase in silicate weathering rates, on account of all three controlling parameters
18 increasing by a large margin in the area, coupled with a predominantly silicate-heavy lithology.
19 In later stages of the model simulation, weathering rate anomalies had mostly retreated to the
20 tropical latitudes, where productivity and runoff anomalies persisted the longest; elsewhere the
21 increase in weathering rates was reduced to below 10% of their value during the third
22 millennium CE.

23 **3.2 Group B results**

1 The purpose of this group of experiments was to assess the importance of including a
2 parameterization for NPP (A0) rather than atmospheric CO₂ concentration (B1), or a weathering
3 scheme based exclusively on temperature and runoff feedbacks (B2). Model output for
4 atmospheric CO₂ concentration and weathering fluxes is shown in Figure 6a. The results
5 strongly suggest that using vegetation productivity rather than CO₂ as a proxy for biological
6 activity makes weathering fluxes much more sensitive to overall climate and environmental
7 changes. Weathering fluxes peaked around year 2200, and the increase for simulation A0 (using
8 NPP) was twice that for simulation B1 (using CO₂), and about three times larger than for
9 simulation B2 (with no biological effect); in other words, adding a deliberate NPP dependence
10 tripled the weathering increase compared to the case using a temperature dependence only. This
11 is likely a result of rapid vegetation expansion in the high latitudes and the appearance of warm-
12 adapted and more productive biomes in the temperate regions, which was taken into account in
13 A0 but not in the Group B model versions. As a result, the recovery time of atmospheric CO₂
14 levels was much faster in A0, and vegetation productivity rapidly dropped below the levels of B1
15 and B2 (not shown). Interestingly, after year 7000 the weathering DIC flux in simulation A0 fell
16 below that of B1, indicating that from that point onward the parameterization in B1 was more
17 effective in removing CO₂ from the atmosphere. This feature does not appear in the 0-D model
18 results, where DIC weathering fluxes always remained higher in the productivity-dependent
19 model version. As mentioned in section 3.1, it is possible that the increased effectiveness of the
20 2-D weathering parameterization (compared to 0-D) is caused by the coincidence of large
21 temperature/runoff increases within areas that also see a large increase in vegetation NPP. This
22 could be diagnosed from model output by isolating all of the factors which affect weathering
23 rates but such an analysis is beyond the scope of this paper. The most logical answer to why the

1 weathering rates in A0 drop below those of B1 is that the temperature (and NPP) in A0 have
2 dropped so much below that of B1 that weathering rates in B1 manage to exceed those in A0
3 despite using a scheme which does not as efficiently represent the strength of the biological
4 enhancement of weathering.

5 Figure 6b displays the time series of ocean and sediment carbon, as well as three parameters
6 which are used to analyze the evolution of calcite sedimentation in the model: CaCO_3
7 production, pore layer portion, and dissolution. In contrast to 0-D versions of the model, there
8 was a clear convergence of all three 2-D curves for ocean carbon content resulting from a
9 substantial drop in weathering rates during the latter half of the simulation period. The rate of
10 increase of CaCO_3 buried mass was slower in model versions with lower weathering rates; this
11 surprisingly differs from Fig 3b where there was not much difference between the three model
12 versions. However, the 0-D curves still displayed a significant lag behind their 2-D counterparts.
13 The pore layer portion remained unchanged during the first thousand model years after the
14 introduction of the 5000 Pg C pulse, thus mirroring the results of *Meissner et al.* [2012]. Higher
15 biological activity and carbonate concentration in the surface ocean due to warmer temperatures
16 was found to lead to a sharp increase in calcium carbonate formation and precipitation; this was
17 balanced by a rising of the carbon compensation depth (CCD) in the deep ocean fueled by the
18 rising acidity of the ocean, which increased the overall dissolution rate of calcite. As the more
19 immediate effects of the carbon emission pulse receded, oceans became cooler and calcite
20 formation weakened, while dissolution kept increasing for another 1000 years. This created an
21 unbalance in the CaCO_3 pore layer fraction which appears from year 4000 onward. Note that
22 even though dissolution rates in the deep ocean exceeded calcite production in the surface layer,

1 there was still an overall increase in CaCO_3 buried mass due to the enormous increase in oceanic
2 carbon content.

3 Figure 7 displays the spatial distribution of CaCO_3 and CaSiO_3 weathering changes at various
4 points of the simulation timeline for model version B1. Several areas of higher weathering from
5 Figure 5 are completely absent (central Eurasia), and some others are greatly reduced (tropical
6 Africa). These are the most important examples of how the vegetation productivity
7 parameterization can greatly enhance carbonate weathering locally, and silicate weathering
8 worldwide (see Figure 4b). Weathering rates are generally higher in A0 throughout the
9 simulation, but it should be noted that in some areas in the final snapshot (year 12,000 CE)
10 weathering in A0 falls below that of B1. Since the only difference between B1 and B2 is the
11 presence of (globally averaged) atmospheric CO_2 concentration as a factor, the equivalent figure
12 for model version B2 (not shown) would have been extremely similar to B1, with the magnitude
13 of warming being a bit higher in B1 given that globally increased CO_2 would augment
14 weathering rates everywhere.

15 **3.3 Group C results**

16 The purpose of this group of experiments was to isolate and compare the individual contributions
17 of carbonate (C1) and silicate (C2) weathering to the global feedback mechanism, and to
18 compare them with a scenario where this negative feedback does not exist (C3). The time series
19 of atmospheric CO_2 concentrations and DIC/alkalinity weathering are shown in Figure 8a. After
20 500 years of roughly similar behavior, the curves diverged into three distinct narratives. By year
21 12,000, about 33% of the emitted carbon was still in the atmosphere for model version C3
22 (constant weathering), whereas about 20% of the carbon remained for the C1 (change in

1 carbonate weathering only), and 10% for C2 (change in silicate weathering only) and A0 (control
2 run). This is due to the immediate effect of carbonate weathering, which increase alkalinity
3 content in the ocean faster than the rate at which the precipitation of calcium carbonate increases.
4 Over timescales of 10^5 years or more, we would expect the C3 curve to catch up to C1 as
5 increased calcite burial releases carbon dioxide back to the ocean, negating the carbon removal at
6 the surface; this outcome is verified in the million-year simulations of Colbourn et al. (2013) but
7 impossible to replicate here due to the time scales involved. The C2 model version yielded very
8 similar results to A0, which included the impacts of both carbonate and silicate weathering. The
9 difference between the two was greater initially, as the additional alkalinity provided by
10 carbonate weathering further enhances the oceanic uptake of CO_2 from the atmosphere, but the
11 gap gradually narrowed as the medium-term impacts of carbonate weathering faded away.
12 Could the model run have been extended to hundreds of thousands of years, we would have seen
13 a return to pre-industrial levels for both the A0 and C2 model versions. Estimates for the
14 lifetime of anthropogenic CO_2 have varied from a few (Sundquist, 1991; Archer et al., 1997) to
15 several (Bernier and Kothavala, 2001; Archer, 2005) hundreds of thousands of years. There was
16 no change in DIC weathering output from C2 since silicate weathering in this model does not
17 increase the DIC flux to the ocean. Alkalinity flux from C1 exceeded that of other model
18 versions towards the end of the simulation period as the slower carbon removal resulted in much
19 warmer surface conditions (due to the longer residence time of carbon dioxide in the atmosphere)
20 compared to other model versions.

21 The evolution of ocean sedimentation is presented in Figure 8b using five model variables: ocean
22 carbon, calcite buried mass, upward/downward flux of calcite, and pore layer portion. Ocean
23 carbon levels remained similar between C1 and C2 during the first two thousand years, after

1 which C1 overtook C2 and eventually A0, despite resulting in the least amount of carbon
2 removal of the three model versions. This is because C1 would send as much DIC into the ocean
3 as alkalinity, which is counterproductive to atmospheric carbon removal. Inversely, C2 removed
4 almost as much carbon as A0 while adding 1000 Pg C less into the ocean, testifying towards the
5 efficiency of silicate weathering in removing carbon from the atmosphere compared to carbonate
6 weathering. Calcite sedimentation followed a very similar evolution to the experiments in Group
7 B (section 3.2), with the calcite pore layer portion remaining unchanged for 1000 years until the
8 upward flux of calcite (dissolution) became larger than the downward flux of calcite
9 (production/precipitation). Here it becomes clear that rock weathering, and in particular, silicate
10 weathering, is crucial in maintaining the stability of the pore layer fraction in the long term.
11 Model version C3, where weathering rates remain constant, produced a much sharper increase in
12 calcite dissolution compared to A0, where both weathering types respond to changes in climate,
13 and the burial of CaCO_3 in sediments occurred much faster in A0 than in C3. Additionally, pore
14 layer portion was better maintained by silicate weathering (C2) than carbonate weathering (C1).
15 These results suggest that the alkalinity flux supplied by silicate weathering is necessary not only
16 for decreasing the oceanic buffer factor (i.e., the concentration of carbonic acid and carbonate in
17 ocean surface water) and allowing the uptake of more CO_2 from the atmosphere, but also to
18 maintain a better balance of the oceanic sedimentary pore layer by mitigating the increase in
19 calcite dissolution in the deep compared to the production rate in the surface layer.

20 **4 Discussion**

21 The weathering scheme introduced here is subject to some caveats relating to the formulation
22 itself, as well as the limitations inherent in the UVic model. Colbourn et al. (2013) carefully
23 discuss the potential misrepresentation of temperature as a factor, especially when other

1 parameters such as vegetation productivity are also taken into account. In particular, it is
2 possible that the temperature dependency for carbonate weathering (equation 7), which was
3 developed empirically from correlating groundwater CaCO_3 concentration with water
4 temperature in various river catchment basins, also captures the coincident changes in vegetation
5 productivity and river runoff, hence making the other factors redundant to a certain extent.
6 Whether this would introduce a significant error to the modeling is questionable, as temperature
7 on its own was shown to have at most a moderate impact on overall changes in weathering rates
8 (see Sect. 3.1).

9 The validity of the other two parameterizations – NPP and runoff – is difficult to assess as the
10 formulations are based on the arbitrary assumption that weathering rates vary monotonically with
11 changes in the two parameters. The representation of the biological enhancement of weathering
12 through changes in vegetation NPP is a daunting task indeed, and neither our understanding of
13 the underlying processes nor the complexity of the UVic model terrestrial module would allow
14 for a parameterization which accurately reflects the underlying mechanisms. For example, the
15 parameterization is meant to represent the physical impacts of root expansion, and the chemical
16 impacts of soil kinetics, on the breakdown of rock into minerals and their eventual dissociation
17 by carbonic acid; therefore an ideal productivity scheme would account for the impacts of
18 various plant types on each of the lithologies in terms of areal coverage, root expansion, and
19 other relevant quantities. It is difficult to assess the uncertainty related to the choice of NPP
20 parameterization, as there is not an equivalent alternative formulation of the biological
21 enhancement of weathering with which to gauge the validity of the results presented here –
22 reverting to CO_2 as the main proxy for biological activity would be arguably a worse choice than
23 NPP.

1 Moreover, it should be noted that the efficiency both the NPP and runoff schemes in our model
2 rely heavily on the initial (steady-state) ratio between weathering and NPP/runoff, meaning that a
3 change in a parameter in an initially low-activity region (such as colder climates) may have a
4 disproportionately higher impact on weathering rates compared to changes in tropical areas. It is
5 possible that the introduction of vegetation in a previously nonvegetated area would introduce a
6 stress likely to drastically increase rock erosion, but this is an effect that would be better
7 represented by directly parameterizing the new plant type as a stress on the underlying lithology.
8 For a better alternative, one could consider a weathering scheme based on the absolute value of
9 NPP/runoff (using for example, a non-linear empirical function linking weathering rate and net
10 primary productivity) rather than the ratio of the current value to the initial value. The
11 development of such a relationship, however, would require a more in-depth investigation of the
12 role of plants, and biotic activity in general, on the physical and chemical erosion of rocks.

13 Another source of uncertainty in our results lies in the UVic model itself. While very well suited
14 to simulate long-term impacts of carbon emissions and increased weathering rates on ocean
15 biogeochemistry, on a shorter time scale (10^2 - 10^3 years) the lack of advanced atmospheric
16 dynamics prevents the model from adapting to the extreme warming brought on by carbon
17 emissions in a manner consistent with our understanding of global climate. Under extreme
18 warming there is a poleward shift of the tropical and subtropical cells and consequent changes in
19 precipitation patterns, leading to a potential overestimate of atmospheric temperature and
20 moisture content changes over tropical regions (see Sect. 3.1). This effect is important mostly
21 between years 2000-3000 CE, and fades away as the brunt of the climate and biogeochemical
22 changes are shifted to the oceans. The model's simplified precipitation scheme also likely

1 affects its ability to simulate runoff changes, which are central to both the initiation and
2 modulation of weathering rates.

3 Terrestrial rock weathering is a complex mechanism with many variables worth considering,
4 many of which have a high degree of interdependence (Walker and Kasting, 1981; Berner, 1991;
5 Lenton and Britton, 2006). In the scheme introduced in this paper for the UVic model, we
6 considered the impacts of temperature, productivity and runoff (all parameters previously
7 examined in zero-dimensional weathering models), along with lithological distribution to drive
8 spatial variability. However, many other factors which affect weathering rates were unaccounted
9 for that could also be relevant in the context of a spatially explicit weathering scheme. Perhaps
10 the most meaningful of all is the consideration of sea level change. It is highly likely that the
11 extreme warming caused by anthropogenic emissions would result in a significant melting of the
12 Greenland and West Antarctic ice sheets (Clark et al., 2016), not only disrupting the freshwater
13 balance in the polar oceans, but also providing enough of a global rise in sea levels along with
14 the thermal expansion of seawater to flood many coastal areas. Many of the low-elevation
15 continental shelves threatened by sea level rise are situated in weathering active, tropical regions,
16 and therefore the interruption of terrestrial weathering due to the flooding of these areas could
17 have a more than trivial effect on global weathering output, thus weakening the response to
18 global warming. Note that the extensive warming could also bring about a decrease in ice sheet
19 area, especially in Greenland, which would open up some potentially very active weathering
20 regions (Kump and Alley, 1994). However, the extent of this areal reduction of ice sheet cover
21 over a few thousand years is likely to be overwhelmingly compensated by the area of land
22 flooded by sea level rise.

1 Another factor of some relevance is the interaction with land biogeochemistry. There has been
2 an extensive discussion in recent years on the role of mid- to high-latitude peatlands in the
3 context of a rapidly warming Earth, especially with regards to the decarbonation of these
4 ecosystems and subsequent release of greenhouse gases in the atmosphere (mostly methane) that
5 could greatly amplify global warming (Le Roux and Shotykh, 2006). While the release of
6 methane by itself does not directly affect terrestrial weathering, there are a variety of soil
7 processes within peatlands which are triggered or amplified by warming and which would have a
8 significant local effect on the chemical dissociation of rocks.

9 There are many other factors which would be worth investigating, ranging from anywhere
10 between the physical break down and grinding of rocks by roots to the chemical enhancement of
11 weathering due to the presence of active reagents (Ridgwell and Zeebe, 2005). For example, a
12 distinction between physical and chemical weathering would allow the inclusion of factors such
13 as altitude, as wind and relief/slope play a major role in physical weathering. The impact of
14 ground frost at higher latitudes also leads to erosion, and could increase weathering rates in
15 colder climates. Finally, one cannot ignore anthropogenic impacts, in particular the spread of
16 modern agriculture, in which crop yields are often boosted using mineral fertilisers and other
17 chemicals, which mix in with the soil water and accelerate the erosion of the bedrock. Other
18 features of the Anthropocene worth mentioning include acid rain and land use change, all of
19 which need to be taken into consideration in order to better represent the modern dynamics of
20 global biogeochemistry. Unfortunately, it is unlikely that most of these factors can be properly
21 integrated in current low- and intermediate-complexity climate models, on account of their
22 requiring a spatial resolution much finer than what most EMICs can offer. For example, the

1 UVic model's $1.8^{\circ} \times 3.6^{\circ}$ resolution cannot resolve physical mechanisms which occur over a
2 single-kilometer spatial scale.

3 **5 Conclusions**

4 A spatially-explicit weathering scheme has been developed and integrated into the University of
5 Victoria Earth System Climate Model (UVic ESCM). The model was constructed in such a way
6 that weathering rates at a certain point are computed based on the difference in temperature,
7 vegetation net primary productivity, and runoff, between that point and pre-determined initial
8 conditions. In our model, those initial conditions were based on pre-industrial runoff and
9 lithology (Amiotte-Suchet et al., 2003), which provides the basis for the two-dimensionality of
10 the model.

11 The model was tested with scenarios of future climate change, using (in most cases) a pulse of
12 5000 Pg C at year 2000 to simulate climate system recovery from anthropogenic emissions and
13 the role of global weathering during the following 10000 years. Overall, the model results
14 suggested that weathering has a negligible effect on atmospheric CO₂ and ocean biogeochemistry
15 on short timescales, but its impact becomes more discernible as we progress to multimillennial
16 timescales. We also found that climate system recovery from carbon emissions was much faster
17 using a two-dimensional model rather than the zero-dimensional model versions used in previous
18 work. Among the various climate factors used in the model, we found primary productivity to be
19 by far the most important, producing an increase in global weathering far higher than a model
20 version using atmospheric CO₂ levels to represent biotic activity, or one where only temperature
21 and runoff changes were considered. This highlights the need for further research to determine
22 whether this effect of biotic activity on physical and chemical weathering is in fact an important

1 real-world process that is independent of temperature and/or runoff change. Lithology itself was
2 also found to be very important, often meaning the difference between a weathering-active and
3 high- and low-weathering region. In terms of global totals, carbonate weathering was found to
4 be more prominent than silicate weathering, mostly on account of weathering-vulnerable rocks
5 being mostly carbonate-weathered. However, our results clearly emphasized that silicate
6 weathering is the only process of the two which has the capacity to fully restore the climate
7 system to pre-industrial levels (on timescales of 10^5 years), thus confirming the findings of
8 Colbourn et al. (2013).

9 This work has established the importance of using a spatially-explicit weathering scheme to
10 better represent long-term changes in carbon biogeochemistry. Our approach, although crude,
11 has demonstrated that weathering can be integrated on the grid-cell level and still produce
12 reasonable results. This study did not take into account the more subtle aspects of spatial
13 variability, such as the impacts of ice sheets, sea level changes, and local factors such as soil
14 activity and topography. These are therefore important processes to include in further analyses
15 of the effect of deglacial weathering changes on ocean biogeochemistry and climate change.

16

17 **Acknowledgements**

18 We thank P. Amiotte-Suchet for providing the dataset for the worldwide rock type distribution
19 for the GEM-CO₂ model, as well as K. Meissner for providing the code for 0-D model versions,
20 A. Mucci for helping us better understand carbonate chemistry, and G. Colbourn for his
21 assistance in understanding the RokGeM model. The support of NSERC Discovery Grants
22 awarded to LAM and HDM is also gratefully acknowledged.

1 **Table captions**

2

3 **Table 1.** Rock type constants used in equations 5 and 6. Here, k represents the weathering rate
4 multiplier, with a higher multiplier signifying a higher concentration of weathering products per
5 unit of runoff (or alternatively, a lower resistance to weathering agents); α denotes the fraction of
6 the given rock type to weather as carbonate rocks. A value of zero means that the rock type
7 consists of silicate minerals only.

8

9 **Table 2.** Description of each experiment carried out in this study. The emission total is the total
10 amount of carbon emissions; the emission total is divided equally among the number of time
11 steps during the emission period. For the biological factor, “NPP” refers to equation 10, “Atm.
12 CO₂” to equation 11, and “None” signifies that this part of the weathering scheme is ignored.
13 Finally, when the CaCO₃ switch is OFF, the amount of carbonate weathering produced by the
14 model is set to its pre-industrial value for the duration of the simulation; similarly for when the
15 CaSiO₃ switch is OFF.

16

1 **Table 2**

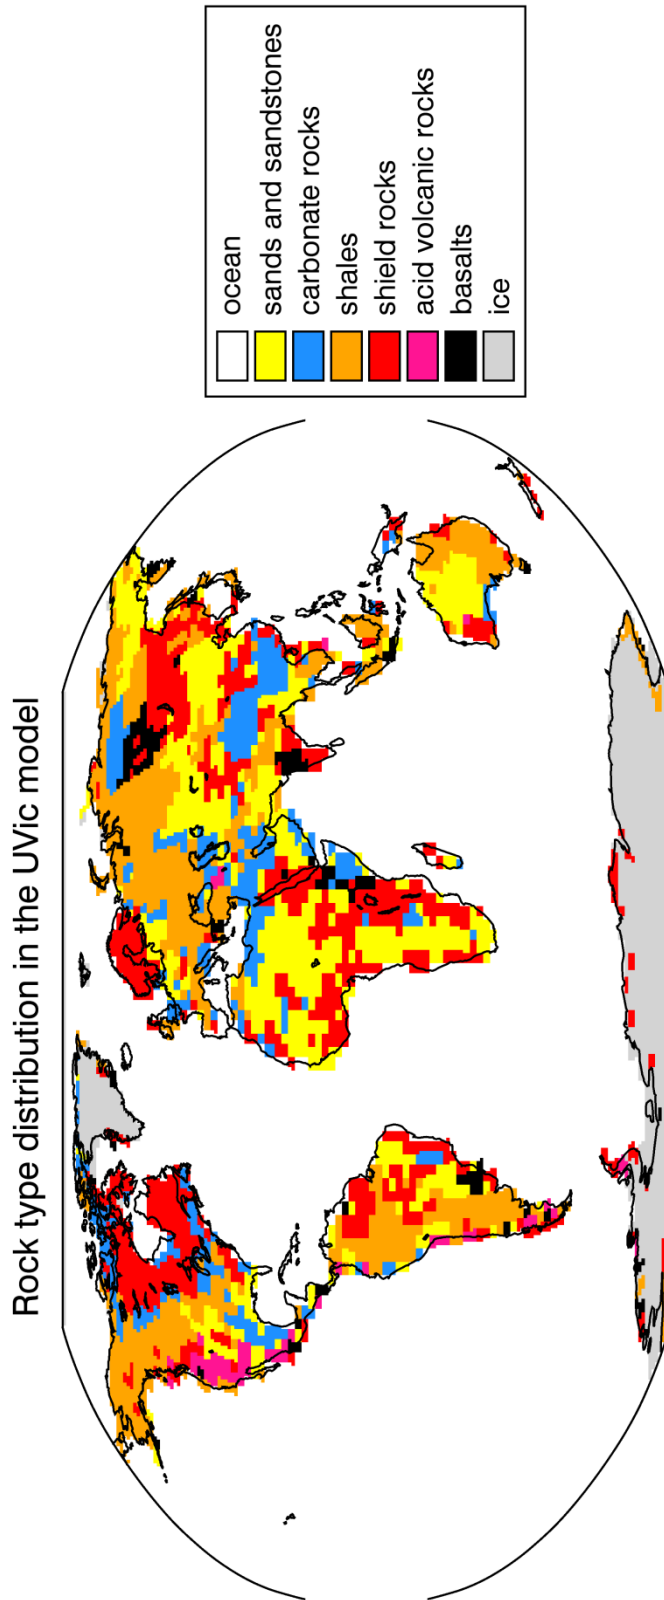

2

Group	Experiment Name	Emission total (Pg C)	Emission period (years CE)	Biological parameter	CaCO₃ weathering switch	CaSiO₃ weathering switch
A	A0	5000	2000-2001	NPP	ON	ON
	A1	1000	2000-2001	NPP	ON	ON
	A2	5000	2000-3000	NPP	ON	ON
B	B1	5000	2000-2001	Atm. CO₂	ON	ON
	B2	5000	2000-2001	None	ON	ON
C	C1	5000	2000-2001	NPP	ON	OFF
	C2	5000	2000-2001	NPP	OFF	ON
	C3	5000	2000-2001	NPP	OFF	OFF

3 Note: The “*” notation refers to zero-dimensional versions of the model using otherwise
 4 identical experimental parameters.
