### Rev 1

“Descriptions of each crop model can be found in the Supplemental material.” (4:7) Please describe the linear model also.
With comments from other reviewers a longer description of the models including the linear model has been added to the main text of the paper. The content relating to the linear model is repeated below.
The linear models use a design that has been used in several previous studies Estes et al. (2013); Lobell and Burke (2010); Wang et al. (2016); Parkes et al. (2017). The models in this study use the robust linear fitting tools in MATLAB (Holland and Welsch, 1977) that are less sensitive to outliers than least squares fitting. The input data for the model have been polynomially detrended before fitting and the log of the yield was taken, this means the models produce relative changes in yield instead of absolute ones. The polynomial detrending used in the models is a two degree polynomial solved for each grid cell. The models solve the equation shown in Eqn 1 where a, b and c are constants for each grid cell and T and P are the seasonal mean temperature and total precipitation respectively.
$Y_{it} = a_i + b_i T_{it} + c_i P_{it}$

It is mentioned that “The four crop models were driven using the outputs of the four bias corrected CORDEX-Africa RCM simulations as listed in table 1. The CORDEX-Africa simulations were driven by ten GCMs as part of CMIP5” (4:19). However, there is no discussion of the uncertainty due to climate forcing from the GCMs and RCMs. It seems important to provide some quantitative measure of it and compare it to the range of results from crop models under the same forcing, which by contrast is discussed extensively.
The relative global warming between the two climates considered is 0.8 K (5:8). What about the local warming in W Africa, which is much more directly relevant here? What is the corresponding local precipitation change? It might be helpful to include a figure that shows the temperature and precipitation seasonal cycle and the modeled changes for the area considered.
These two comments are linked and have therefore been responded to together. A series of tables has been added to the SI showing the mean temperature change and IAV along with the change in total seasonal precipitation and IAV. The following descriptive text has been added from 2:28.
The precipitation and temperature changes for growing season of maize in the grid cells where maize is analysed in the GCMs, RCMs and GCM-RCM pairings are shown in SI Tables 1-3. The mean temperature change across the 16 member GCM-RCM ensemble is +0.98 K with a model spread of 0.3 K. The mean precipitation change across the ensemble is +0.65 cm/season with a model spread of 1.70 cm/season. This is a 1.2% increase in precipitation with a spread of 6%.

To simulate high temperature stress resistance the GLAM is rerun with the high temperature stress routine disabled” (6:22) but this situation is biologically impossible. How would the conclusions change if only more realistic stress adaptation were considered?
--

This is a limitation of the model and we have clarified this in the description of the model in the main text of the manuscript.

To simulate a crop resistant to high temperature stress GLAM is rerun with the high temperature stress routine disabled, a description of high temperature stress in flowering is found in Challinor et al (2005). Disabling the high temperature stress routine produces an unphysical crop and is used to give guidance on the importance of high temperature stress.

What is the meaning of “does not suffer from spread from the input data” (7:6)? Also, within the context of this work the “successful” performance of ORCHIDEE-Crop is not very encouraging, as it was run for only one of the three crops considered.

ORCHIDEE-Crop like GLAM has only been validated for maize, therefore it is only used for maize. The wording used should be rephrased to prevent confusion and the following text has been used in place.

ORCHIDEE-Crop replicates the observed IAV and in contrast with the other process based models, GLAM and Sarra-H. The mean yields however do show a significant bias.

The yield gains predicted herein need to be considered as part of longer term trends that show severe yield reductions as the 21stst [sic] century progresses.” (8:7) It would be good to provide citations.

The spelling mistake has been corrected and the following references have been added to the the sentence.

(Challinor et al.,2014; Knox et al., 2012)

Figures 4-6: It’s impossible for the variability or failure rate to be less than zero. So the color scale should start no lower than zero.

In action to comments from other reviewers, the heatmaps have been removed and replaced new figures and tables. The remaining heatmaps are shown below.

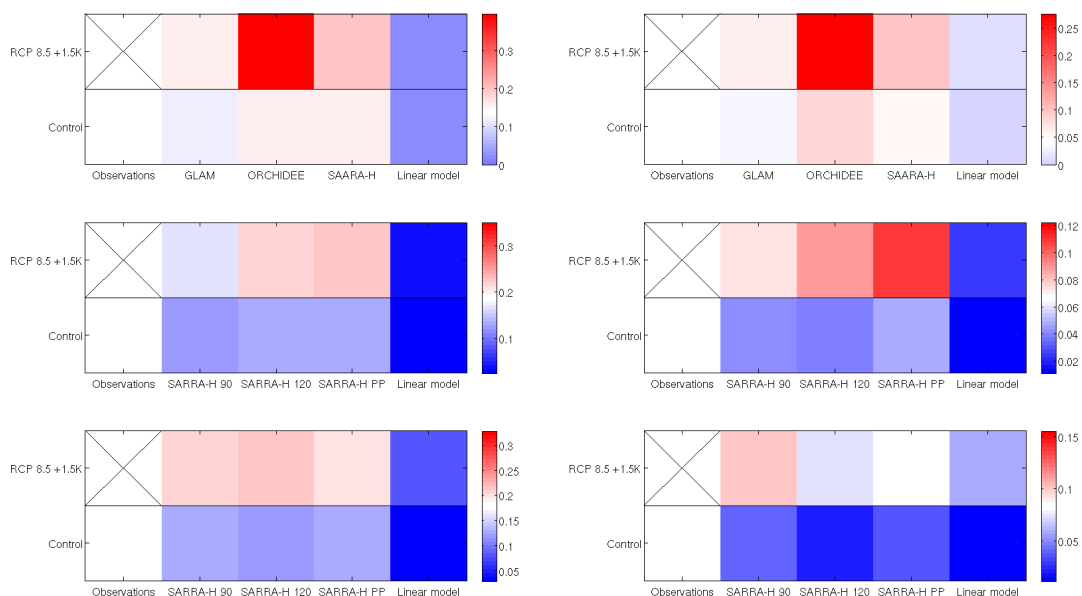

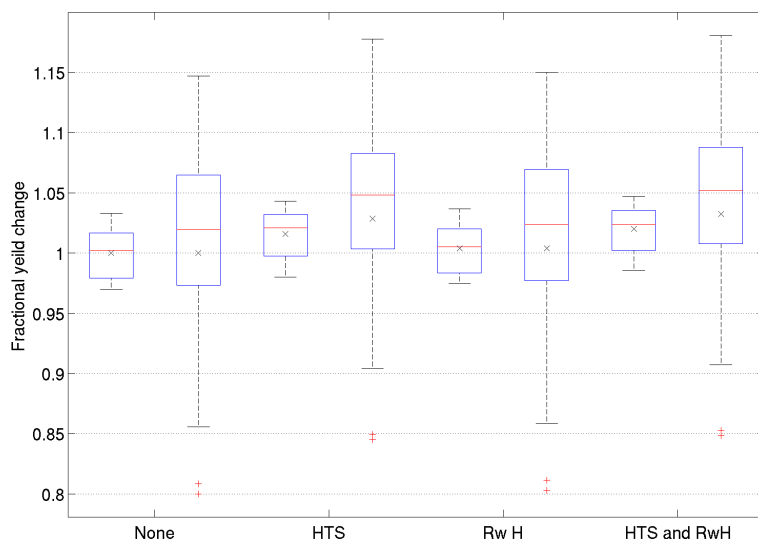

Figure 7 is hard to understand. The caption should explain “Impact in current climate” and “Impact of adaptation”, and the mean yield and number of years between crop failures should probably be shown in different panels since they are fundamentally different quantities.

Figure 7 has been rebuilt as a single boxplot with a detailed caption explaining the content. With two boxplots it was not easy to see the difference between the adaptation methods. The new plot and caption are shown below.

Efficacy of adaptation methods for maize in GLAM. HTS is high temperature stress adapted crops, Rw H shows crops with rainwater harvesting, HTS and Rw H shows both adaptation methods in use. Each box shows the fractional yield change relative to the unadapted crop with the boxplots showing the range across the 6 member GCM-RCM ensemble. The pairs of boxes show the relative change in yield for the adaptation method in the historic climate (left) and the future climate (right).

Tables 3-5: Please also include and discuss the region-wide mean change (production-weighted sum of the by-country changes).

The tables have been updated and new content inserted into the results and discussion sections of the manuscript.

Sample changes made to manuscript

### Rev 2

1. Information about crop models: The basic characteristics of the crop models should be given in the main text (Which models do account for CO<sub>2</sub> fertilization? etc.). The predictors and equations of the statistical models have to be provided.

The model descriptions have been moved from the SI to the main text and a description of the linear models added.

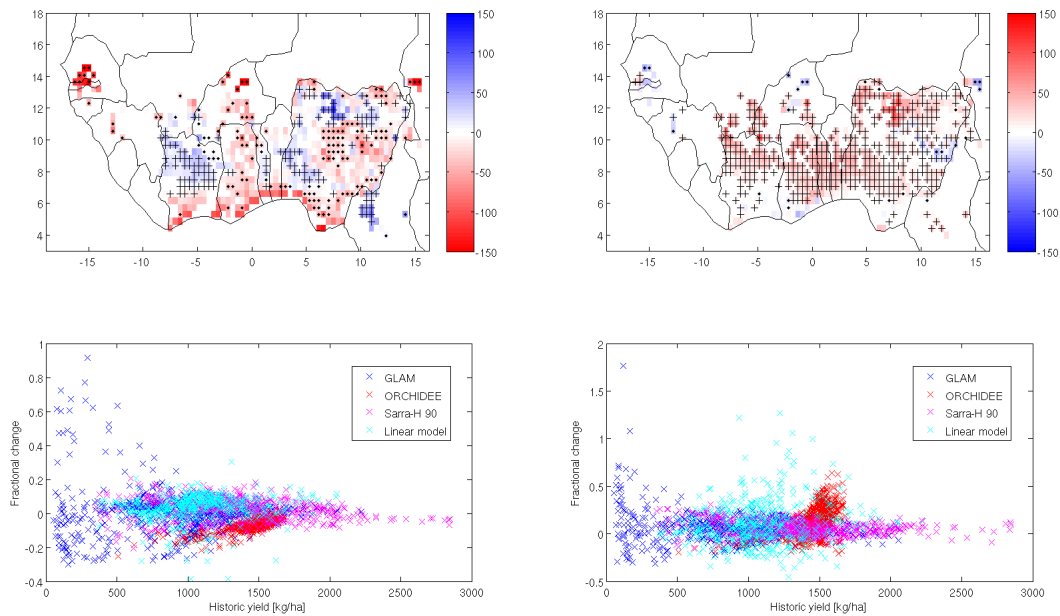

GLAM and ORCHIDEE-Crop both respond to carbon dioxide fertilisation and ORCHIDEE-Crop has nitrogen fertiliser inputs as part of the simulated crop growth.

The linear models use a design that has been used in several previous studies Estes et al. (2013); Lobell and Burke (2010); Wang et al. (2016); Parkes et al. (2017). The models in this study use the robust linear fitting tools in MATLAB (Holland and Welsch, 1977) that are less sensitive to outliers than least squares fitting. The input data for the model have been polynomially detrended before fitting and the log of the yield was taken, this means the models produce relative changes in yield instead of absolute ones. The polynomial detrending used in the models is a two degree polynomial solved for each grid cell. The models solve the equation shown in Eqn 1 where a, b and c are constants for each grid cell and T and P are the seasonal mean temperature and total precipitation respectively.

$$Y_{it} = a_i + b_i T_{it} + c_i P_{it}$$

2. Entire distribution of changes in crop yields: Instead of showing the heat maps of mean changes it would be much better to report the results of the individual models to illustrate the spread in the projections and allow for a risk assessment that does not only depend on ensemble mean changes but also on the range of plausible projections. For example, each individual simulation could contribute one dot to a scatter plot of present-day mean yields (x-coordinate) against relative changes in yields from present- day climate to a “1.5° C world” (y-coordinate). All simulations generated by one crop model could be shown in one color. Such plots could be provided for the entire region or individual countries. I consider it particularly problematic to simply average across models accounting for CO<sub>2</sub> fertilization effects (GLAM and ORCHIDEE-crop (I assume although it is not stated in the SI)) and others that do not (Sarra-H and the statistical models (I assume)). This could be avoided on this way.

Combined with requests from other reviewers we have built the following plots that show the map of yield and IAV changes along with scatter plots suggested above. The maize plot is shown below while the millet and sorghum plots have also been added to the manuscript.

Change in maize yield and yield IAV between the historic and future climates. The top left shows the change in yield where + indicates that in three crop models the change will be positive and · indicates that in three crop models the change will be negative. The top right is the same as the top left except for IAV instead of yield. The units of the colour bar in the top plots is kg/ha. The bottom left shows the fractional change in yield against yield for all analysed grid cells. The bottom right shows the fractional change in yield IAV against yield for all analysed grid cells.

3. Representation of present day management in process-based models: The paper needs a more detailed discussion to what degree the process-based crop models represent present day management (fertilizer input, specification of growing seasons, representation of multi-cropping). Is there additional information about growing season or fertilizer input to evaluate the models assumptions?

Extra detail has been added in the crop models description section of the manuscript

GLAM and ORCHIDEE-Crop both respond to carbon dioxide fertilisation and ORCHIDEE-Crop has nitrogen fertiliser inputs as part of the simulated crop growth.

The planting and harvest dates for the crop models were determined using data generated as part of the Global Gridded Crop Model Intercomparison project (Elliott et al 2015). The crop models all simulate crops based on a single planting and harvest without multicropping.

4. Inter-crop model spread of projected changes: It is usually hard to really explain model differences. It may be impossible. However, any idea would be extremely valuable and should be discussed to advance the field and create a better understanding of the processes and potential deficits in their representation.

A new section describing the main differences in the models has been added.

Differences in the crop models

Both GLAM and ORCHIDEE-Crop were used to simulate maize, SARRA-H and the generalised linear models were used to simulate maize, sorghum and millet. GLAM and ORCHIDEE-Crop both respond to carbon dioxide fertilisation and ORCHIDEE-Crop has nitrogen fertiliser inputs as part of the simulated crop growth. The crop models all simulate crops based on a single planting

and harvest without multicropping. GLAM and the linear models use observational yield as an input, in both cases the input yield is detrended using a two degree polynomial before use. This detrending removes consistent trends such as management changes and technological improvements. GLAM unlike the other models was calibrated specifically for these simulations whereas ORCHIDEE-Crop and SARRA-H used pre defined parameter sets. The SARRA-H parameters were based on a study area in Burkina Faso. The process based models are time dependent and respond to the arrival of the monsoon, the linear models however only use the seasonal total precipitation. Linear models suffer with reduced accuracy outside the parameters space used to train them. In the short term linear models are not notably worse than process based models (Lobell and Asseng,2017).

The differences in the crop models and inputs have an influence on the results. From Figure 1 GLAM shows a greater spread of yield change with climate change than the other models whereas ORCHIDEE-Crop and SARRA-H are more consistent under climate change. The yield changes in ORCHIDEE-Crop and GLAM are also influenced by the carbon dioxide fertilisation effect and in its absence the projected yields are expected to be lower. The IAV results show greater spread in the linear models than the process based models, this is a result of the simple parameters in the linear models. The results in Figure 5 show that GLAM has a stronger negative response to precipitation loss than the other models. The temperature results for all models show a downward trend in yield with increasing temperatures. The lack of variability in the linear models is shown in Figure 4 where they consistently underestimate crop failure rates. ORCHIDEE-Crop has a smaller IAV than the other process based models which means the crop failure limit is much higher than in the other models. This results in ORCHIDEE-Crop finding a significant increase in the number of crop failures. As the ORCHIDEE-Crop IAV is closest to the observed IAV (Table 3), this indicates that GLAM and SARRA-H are likely to underestimate the number of future crop failures. For Figures 2 and 3 the country scale yields in the historic inputs can be clearly seen in the linear models as opposed to the spread of yield values in SARRA-H.

5. Comparison of return periods of crop failure: How are the return frequencies of crop failures derived? I assume that they are determined from crop-model specific samples of  $N = 16$  climate simulations  $\times 20$  years = 320 data points. In this case it could be an artefact that the distribution of yields at 1.5° C of global warming is wider (and potentially less normal) than the associated present-day sample: The 1.5° C distributions simply comprises the inter-climate model spread of the simulations which is reduced in the present-day sample due to the underlying bias-correction. To avoid this artefact the change in variability would have to be estimated within each individual climate model. Averaging across the different climate models would have to be done afterwards. However, that approach would reduce the sample size to only 20 (or 30) years, probably not enough to robustly estimate crop failures in the proposed way. So it may only be possible to compare the standard deviations (or percentiles) of both 20 (30)-year samples (present-day vs 1.5° C) as an alternative measure of the variability.

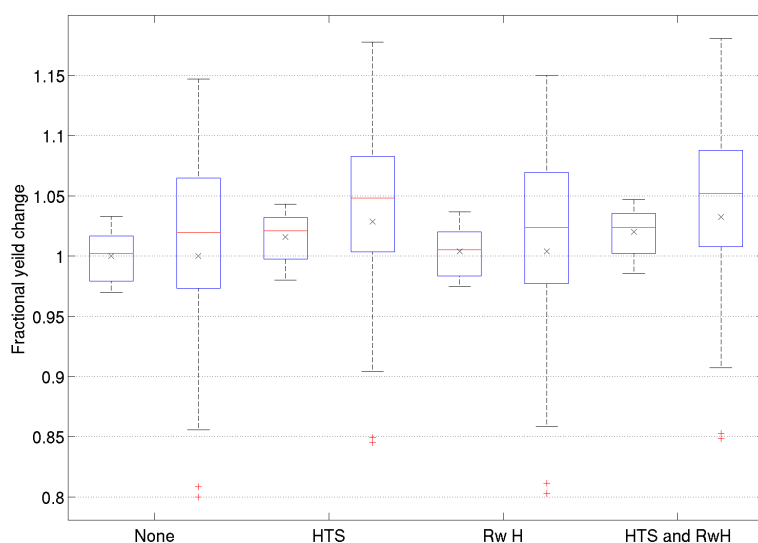

Every grid cell is checked for a crop failure against the crop failure limits determined by the historic simulations. The historic simulations are used instead of the observations as a sufficiently high or low bias would overwhelm the IAV and cause either zero or total crop failure. The number of crop failures is then totalled across the simulation and divided by the total number of simulations to give a crop failure fraction. The inverse of the crop failure fraction is the return time of crop failure. The following text has been added to the manuscript to clarify this.

The number of crop failures is recorded for each grid cell and the total across the domain is calculated. The total number of simulations for a crop model is the number of analysed grid cells multiplied by the number of years of simulation. The total number of crop failures is divided by the total number of simulations to give a fractional number of crop failures, this is the crop failure rate

with units of failures per grid cell per year. The inverse of the crop failure rate is the mean return time for a crop failure.

6. Assessment of adaptation methods: Figure 7 is hard interpret. I think it would be better to 1) show the effects of the on present-day distributions in one panel and 2) show the effects on the 1.5° C distributions in a second panel. In each panel the 16 values of simulated yields (from the 16 climate model simulations) for one model setting could be shown in a box plot such that the first panel would include four of them (one from the default simulation and three from the alternative ones). The second panel could show the associated box plots of relative changes in yields.

Figure 7 has been rebuilt as a single boxplot with a detailed caption explaining the content. With two boxplots it was not easy to see the difference between the adaptation methods. The new plot and caption are shown below.

Efficacy of adaptation methods for maize in GLAM. HTS is high temperature stress adapted crops, Rw H shows crops with rainwater harvesting, HTS and Rw H shows both adaptation methods in use. Each box shows the fractional yield change relative to the unadapted crop with the boxplots showing the range across the 6 member GCM-RCM ensemble. The pairs of boxes show the relative change in yield for the adaptation method in the historic climate (left) and the future climate (right).

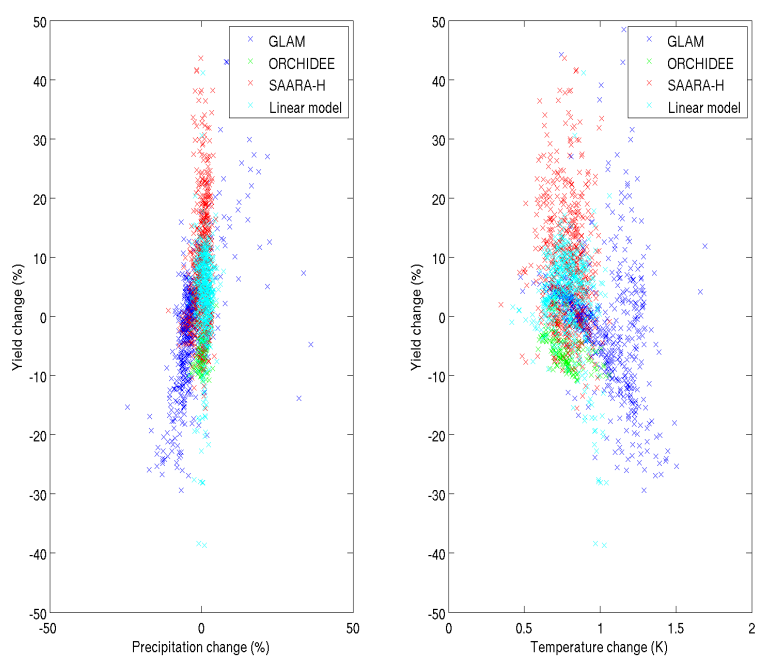

Given the uncertain representation of the current present-day management in the crop models and the artificial turn-off of the heat stress routine in GLAM I am wondering whether the analysis could be really considered as an adaptation scenario. It may be better to frame it as a test whether the simulated yield changes are more driven by temperature stress or water scarcity. In this sense one could think about a more general indicator that measures these stresses in the process-based simulations. It would be a way to include the other models, too. It would be good to include the other models in this assessment.

We have kept the specific adaptation results separate for GLAM as they are model specific. We have however added scatter plots of yield change (%) against precipitation change (%) and temperature change (K) to show the responses of the models. Furthermore the adaptation results have been expanded to highlight that the rainwater harvesting may be insufficiently supply water to counteract the precipitation losses in the future climate.

The results in Figure 5 show the responses of the maize yield to changes in precipitation and

temperature change for four crop models. To highlight the responses of precipitation changes between -50% and +50% the x-axis of the left figure is truncated, a full version of the figure is shown in SI Figure 2. The maize yields in all models show an increase in yield with increasing precipitation. A negative trend is also present with increasing temperatures. The differences between the crop models can be seen in these figures. The results in ORCHIDEE-Crop show less variability than SARRA-H, GLAM or the Linear models and have a strong negative yield response for a limited temperature change. The temperature change experienced by the crops simulated in GLAM covers a larger range than the other models and the positive relationship between precipitation and yield is also shown. Water scarcity has a smaller impact on SARRA-H and the Linear models than in GLAM or ORCHIDEE-Crop and the SARRA-H results do not show a strong negative response to higher temperatures.

This result needs to be considered alongside the results in Figure 5 which show a strong negative precipitation response in GLAM, indicating that the rainwater harvesting routine, while providing some extra water does not provide enough to counteract the precipitation changes in the future simulations.

More specific comments: P2L9-P3L2: Add the level of global warming or at least the emission scenario and the timing when discussion the crop yield changes found in other studies. Do they account for the CO2 fertilization effect or not? Are projections based on the assumption of no adaptation? All the reported changes are conditional on these assumptions and are meaningless otherwise.

The requested details have been added into the description of the existing literature

Specific comments:

P2L9: Crops could also be imported. Add the information to what degree the considered countries currently fulfill their demand.

Using FAO stats for 2005 in West Africa, all countries are currently net importers of cereals with Gambia and Senegal close to three times the regional average of 41 kg/person. With yield changes

expected to be smaller than population changes the amount of imported food required will therefore need to increase. This has been commented on and the FAO cited in the manuscript.

To maintain current levels of food intake the crop yields in West Africa will need to increase in step with the increasing population. All countries within West Africa are currently net importers of cereals indicating that their current production is insufficient to meet demand (UN FAO)

P2L12 : Add the information which of the considered crops is C3 or C4 as the differences in CO2 fertilization effects are discussed before.

The crops are all C4 and this is now mentioned in the manuscript where we describe our work

In this paper we use four crop models simulating three crops and driven by meteorological outputs from several regional climate models. Three C4 crops have been selected for this analysis; maize, sorghum and millet.

P3L5: I am wondering whether the aim of the paper really is to “identify and quantify some of the sources of uncertainty in the West African agricultural system as the global climate passes 1.5° C”. Is it not a probabilistic projections of the impacts of 1.5° C of global warming on crop yields?

We agree and this has been changed to the statement below

The aim of this paper is to produce probabilistic projections of West African crop yields as the global climate passes 1.5 K above the pre-industrial control

P3L15: Is there a trend in the reported crop yields, e.g. due to technological progress? Such a trend is probably not expected from the crop model simulations that do not account for these effects. Could that explain part of the difference between the present day simulations and observations? The technology or management induced trend in the observations would also lead to a wider distribution of the observed present-day yields and the simulated ones. How do you account for these effects?

There are a number of trends. The existing crop yields are used as inputs for two models: GLAM and the linear models. For both we detrend using a 2 degree polynomial to remove technology terms, management changes and increased mechanisation. The remaining data is expected to be primarily climate driven. This is described in the crop model section of the manuscript.

GLAM and the linear models use observational yield as an input, in both cases the input yield is detrended using a two degree polynomial before use. This detrending removes consistent trends such as management changes and technological improvements.

P5L11-13: are the differences due to different warming levels considered in these studies?

We use RCP8.5 which is the most severe of the CMIP5 warming levels, therefore it is unlikely that the scenario is less severe than the average of a meta-analysis. The earlier projected time of our results is likely the reason that the results are not as severe as they are in a meta-analysis at 2050. This has been clarified in the text.

The yield losses in GLAM and ORCHIDEE-Crop are smaller than the mean reported in the meta-analysis by Knox et al. (2012). The Knox et al. (2012) results are for crops in the 2050s and therefore our results are expected to be smaller as they are for a closer time horizon. A second meta-analysis by Challinor et al. (2014) presents results by temperature change, our results at 1.5 K are within the range of results found in their analysis.

P5L14: How is the IAV calculated? See potentially associated problems mentioned in the general

comment above. Differences in the variability of observed and simulated crop yields could also be induced by the technological progress affecting the observational data but not represented in the observations or differences in the variability of the climate forcing compared to the observed weather fluctuations. To what degree does the bias-correction adjust the variability of the simulated climate to the variability of the observed climate?

The IAV is the standard deviation of the crop yields, averaged over the domain. The observed crop yields have been detrended to remove non-climate signals as described in the crop modelling section. The multisegement approach of the bias correction will adjust the simulated variability to closely match the observed variability and in doing so removes a number of 'drizzle' events from the record and increases the intensity of wetter events to match the observations.

P6: There should be some more detailed information about the representation of high temperature effects within GLAM.

This information is now in the main manuscript

The high temperature stress at flowering routine was enabled, if the maximum daily temperature is above 37 C the yield is reduced, above 45 C the yield is set to zero (Challinor et al 2005,2015). To test the importance of high temperature stress during flowering, this routine is disabled.

Section 1 of the SI What does it mean that “GLAM used the maize yield data as an input” (SI)? Is the model calibrated to reproduce reported yields in the historical period when forced by observational climate data?

This is correct and has been clarified in the updated manuscript.

GLAM and the linear models use observational yield as an input, in both cases the input yield is detrended using a two degree polynomial before use. This detrending removes consistent trends such as management changes and technological improvements.

Minor issues: P2L4: “or” instead of “of” P2L9: “need to increase” instead of “need increase” P2L19: change “predicted” to “projected” as the results are conditional on the emission scenario. P3L9: “Two adaptation methods. . .” instead of “The use of two adaptation options. . .” P3L18: Would be good to directly name it RCP8.5 P4L26: “With increases” instead to “with to increases” P6L9: “simulation for the historical period” instead of “Simulations in for the historical period” P6L16: Change “predicted” to “projected” P6L32: Delete “agree” Caption of Figure 1: I do not understand the sentence “Sarra-H indicates the model simulating the 90 day variant of maize.”

These corrections have been made, with the exception of the figure captions which have been replaced by new figures and captions.

Sample changes made to manuscript

### Rev 3

1. The methodology is unclear and incomplete. It lacks the necessary details to fully understand the experiment design and the results. For example, there is no explicit information about the statistical model used in the study. We don't know what form this model is and how it works in the study.

The linear model has now been described in the manuscript with the content below.

The linear models use a design that has been used in several previous studies Estes et al. (2013); Lobell and Burke (2010); Wang et al. (2016); Parkes et al. (2017). The models in this study use the robust linear fitting tools in MATLAB (Holland and Welsch, 1977) that are less sensitive to outliers than least squares fitting. The input data for the model have been polynomially detrended before fitting and the log of the yield was taken, this means the models produce relative changes in yield instead of absolute ones. The polynomial detrending used in the models is a two degree polynomial solved for each grid cell. The models solve the equation shown in Eqn 1 where a, b and c are constants for each grid cell and T and P are the seasonal mean temperature and total precipitation respectively.

$$Y_{it} = a_i + b_i T_{it} + c_i P_{it}$$

Moreover, the interannual variability of yield is analyzed in the future based on projections from climate models. But I am not sure whether climate variability and their impacts on yield can be captured by the model's future projection, given that signals like ENSO may not be well captured.

The variability in the input data has been restricted by bias correcting the data. The models have variability that is close to the observations. The monsoon is the primary precipitation source in the region and this is typically a weakness of models. The CORDEX simulations have been shown to perform well at replicating the large scale features including the IAV in precipitation over West Africa. Biases exist in the CORDEX output and this is one of the reasons we have bias corrected the data. To clarify this, the following text has been added.

The CORDEX-Africa simulations were found to perform well at replicating the large scale features of the West African climate including the inter annual variability in precipitation (Diaconescu et al., 2015). The precipitation in West Africa is primarily driven by the north-south motion of the monsoon (Nikulin et al., 2012). The CORDEX-Africa models were found to contain biases despite their good performance and therefore bias corrected model output were selected for further analysis (Gbobaniyi et al., 2014).

2. The analysis and results are kind of unbalanced. Three crops are included in the study, but most of the figures and results are about maize while less attention has been given to other crop and their results are placed in SI.

The figures have been consolidated and placed in the main text.

The ensemble approach using climate data of 16 combinations should help understand the

uncertainty in the results. However, there is little discussion about uncertainty (e.g., from climate input data or model itself). And surprisingly, there is no error bar or confidence level reported in the results. Discussion section needs to include more content to dig into the inconsistencies and discrepancies in the results across the models and across different crop types.

We have confidence levels on the tables of results and the yield changes where discussed. We have also inserted a paragraph on the inter-model differences and the impacts of these differences.

3. The figures in the manuscript are poorly designed, which undermine the readability. Many figures can be combined. Results of three crops can be combined in one figure. The colormap used in the heat map is problematic. Fig 7 is hard to follow. The authors have to think about how to improve the figures to make them more effective in conveying key information and in the meantime easy to read.

New scatter plots of yield and IAV have been created and are shown below. Figure 7 has been reworked into a new box plot.

P1 L4-5: Please specify recent historical and near term future.

The dates have been added for the historic time period, we have instead specified the temperatures as this manuscript is based on SWLs.

An ensemble of near term climate projections are used to simulate maize, millet and sorghum in West Africa in the recent historic (1986-2005) and a near term future where global temperatures are 1.5 K above pre industrial.

P1 L6: "The mean yields are not expected to alter significantly". Where does this expectation come from? This contradicts the results of this study.

This line has been removed and the abstract reworked the full abstract is shown in the comment below.

The abstract needs more work. Please clearly define the science question, explain the methods used and the results.

The abstract has been developed and is shown below.

The ability of a region to feed itself in the upcoming decades is an important question. The West African population is expected to increase significantly in the next 30 years. The responses of crops to short term climate change is critical to the population and the decision makers tasked with food security. This leads to a three questions, How will crop yields change in the near future? What influence will climate change have on crop failures? Which adaptation methods should be employed to ameliorate undesirable changes?

An ensemble of near term climate projections are used to simulate maize, millet and sorghum in West Africa in the recent historic (1986-2005) and a near term future where global temperatures are 1.5 K above pre-industrial to assess the change in yield, yield variability and crop failure rate. Four crop models were used to simulate maize, millet and sorghum in West Africa in the historic and future climates.

Across the majority of West Africa the maize, millet and sorghum yields are shown to fall. In the regions where yields increase the variability also increases. This increase in variability increases the likelihood of crop failures, which are defined as yield negative anomalies beyond one standard deviation during the historic period. The increasing variability increases the frequency of crop failures across West Africa. The return time of crop failures falls from 8.8, 9.7 and 10.1 years to 5.2, 6.3 and 5.8 years for maize, millet and sorghum respectively.

The adoption of heat-resistant cultivars and the use of captured rainwater have been investigated using one crop model as an idealised sensitivity test. The generalised adoption of a cultivar resistant to high temperature stress during flowering is shown to be more beneficial than using rainwater harvesting.

The first paragraph needs to have more references and to be better organized. Some content such as monsoon is irrelevant to the topic of this study.

The monsoon is the primary water source for the crops grown in West Africa is therefore important to the study.

The introduction has been reorganised to flow better, we now discuss the large scale problem, and the challenges faced in the region. This is followed by an introduction to the regional climate, the adaptation methods that people may use and then introduced the carbon dioxide fertilisation effect. We have also added a number of references.

P2 L4 heat- and drought-resistant

This has been corrected

P2 L19-20: references

Reference to Rippke et al added

P3 L23-25: If 10 out of 16 combinations are based on RCA4. Why is it designed this way? My concern is that the results from the ensemble experiment would largely depend on the performance of RCA4, making the results biased to RCA4.

The experiment uses the full set of CORDEX data that were subsequently bias corrected as part of HELIX. We use the full ensemble as subsampling was considered to be less optimal. The CORDEX simulations are not k-complete and we used every experiment that we had access to. The alternatives are, using only RCA4 to remove the RCM as a source of variability, or restricting to the GCMs that used multiple RCMs but only CNRM-CM5, MOHC-HadGEM2-ES and MPI-ESM-LR used both RCA4 and CCLM.

P3 L30-33: The varying CO2 levels could affect the mean yield response as well as the variability under warming. This needs to be discussed.

This is now discussed in the results section

ORCHIDEE-Crop and GLAM simulate responses to carbon dioxide fertilisation. Both models

project a small reduction in yield in future climates, the magnitude of which has been reduced by the increase in yield from carbon dioxide fertilisation. Carbon dioxide fertilisation increases the yield when the crop is limited by carbon dioxide. If the crop is water limited then the carbon dioxide fertilisation will have a smaller effect on yield.

Section 2.2: more information about the four crop models need to be provided. For example, at least to differentiate process-based crop models and the statistical models. Another question is if the results from the statistical model are comparable with that from the process-based models, as the mechanisms drive the change could be different. This needs to be discussed.

More detail about the crop models have been added to the text in both the methods and the discussion

#### Differences in the crop models

Both GLAM and ORCHIDEE-Crop were used to simulate maize, SARRA-H and the generalised linear models were used to simulate maize, sorghum and millet. GLAM and ORCHIDEE-Crop both respond to carbon dioxide fertilisation and ORCHIDEE-Crop has nitrogen fertiliser inputs as part of the simulated crop growth. The crop models all simulate crops based on a single planting and harvest without multicropping. GLAM and the linear models use observational yield as an input, in both cases the input yield is detrended using a two degree polynomial before use. This detrending removes consistent trends such as management changes and technological improvements. GLAM unlike the other models was calibrated specifically for these simulations whereas ORCHIDEE-Crop and SARRA-H used pre defined parameter sets. The SARRA-H parameters were based on a study area in Burkina Faso. The process based models are time dependent and respond to the arrival of the monsoon, the linear models however only use the seasonal total precipitation. Linear models suffer with reduced accuracy outside the parameters space used to train them. In the short term linear models are not notably worse than process based models (Lobell and Asseng,2017).

The differences in the crop models and inputs have an influence on the results. From Figure 1 GLAM shows a greater spread of yield change with climate change than the other models whereas ORCHIDEE-Crop and SARRA-H are more consistent under climate change. The yield changes in ORCHIDEE-Crop and GLAM are also influenced by the carbon dioxide fertilisation effect and in its absence the projected yields are expected to be lower. The IAV results show greater spread in the linear models than the process based models, this is a result of the simple parameters in the linear models. The results in Figure 5 show that GLAM has a stronger negative response to precipitation loss than the other models. The temperature results for all models show a downward trend in yield with increasing temperatures. The lack of variability in the linear models is shown in Figure 4 where they consistently underestimate crop failure rates. ORCHIDEE-Crop has a smaller IAV than the other process based models which means the crop failure limit is much higher than in the other models. This results in ORCHIDEE-Crop finding a significant increase in the number of crop failures. As the ORCHIDEE-Crop IAV is closest to the observed IAV (Table 3), this indicates that GLAM and SARRA-H are likely to underestimate the number of future crop failures. For Figures 2 and 3 the country scale yields in the historic inputs can be clearly seen in the linear models as opposed to the spread of yield values in SARRA-H.

Figure 1: (1) Since the red and blue color already represent negative and positive changes, it may not necessary to use symbols (cross and dot) to denote agreement for negative and positive changes separately. (2) Fig 1 and 2 and be combined to include both mean change and IAV. (3) I would suggest trying to include all four crops in the figure using 8 panels.

The plots have been reworked into new panels to give even attention to all three crops. We have 3 crops and show 3 figures containing 4 panels each. The new panels are maps of yield and IAV

along with scatter plots coloured by model.

P4 L24-25: Unless those place names are shown on the map, they make little for people like me who is not familiar with the geography of West Africa. And this might be the case for most readers.

A figure has been added to the SI and referenced in the results section.

An annotated map of the analysed area is shown in SI Figure 1.

P4 L26: Avoid placing the results in SI unless there is a strong reason to do so. Since millet is one of the three crop types in the study, the results should appear in the main text.

As part of earlier responses we have moved several millet and sorghum results into the main text

Fig 3-6: (1) the current blue-to-red contrast type of colormap is problematic. It is not suitable to display a continuous range of yield value (not yield change). It creates unnecessary visual confusions. For example, What is the white color? Does it mean no value or the value around 1700? Please use other colormaps, there are plenty alternatives to choose. (2) Heat map here may not be a good choice to represent quantitative information . . . The difference between history and future is very hard to see. The authors should consider redesigning this figure or at least display the exact number in the heat map.

The yield and IAV heatmaps have been replaced by new figures and tables.

P5 L11: Please specify the results from Knox and Challinor results? Is that a model result, empirical study, field experiment, or meta-analysis? What did they find and how their results are connected here?

This has been expanded and clarified

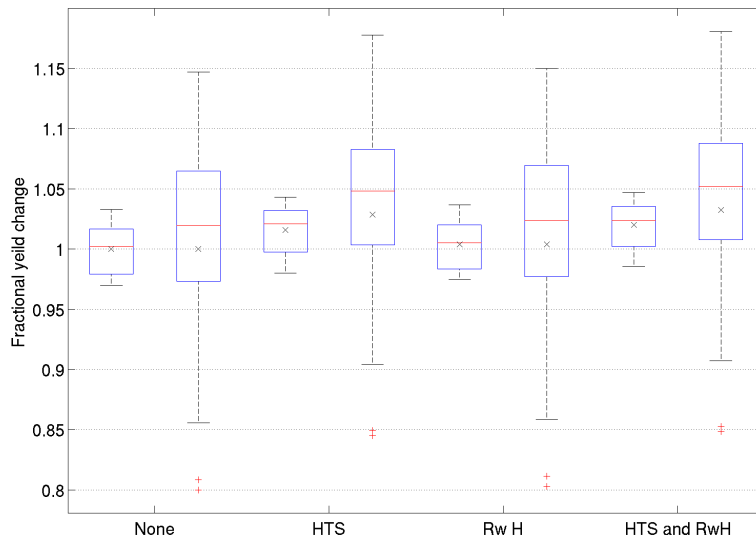

The yield losses in GLAM and ORCHIDEE-Crop are smaller than the mean reported in the meta-analysis by Knox et al. (2012). The Knox et al. (2012) results are for crops in the 2050s and therefore our results are expected to be smaller as they are for a closer time horizon. A second meta-analysis by Challinor et al. (2014) presents results by temperature change, our results at 1.5 K are within the range of results found in their analysis.

P5 L24: Please justify the definition of crop failure using 1 and 1.5 standard deviations of yield. Is the std threshold calculated using observations?

1 and 1.5 have been used in previous studies by the authors. The standard deviation is from the historic results per model. Otherwise biases in the model results would dominate over the yield changes. A citation of Parkes et al 2015 has been added too.

Fig 7. The legend is incomplete. Please add legends for all symbols including cross, circle, etc. I don't understand how to read this figure... What is the variable on x and y axes and their units? Please add more information in the caption.

Figure 7 has been reworked as a boxplot instead of the scatter plot.

Efficacy of adaptation methods for maize in GLAM. HTS is high temperature stress adapted crops, Rw H shows crops with rainwater harvesting, HTS and Rw H shows both adaptation methods in use. Each box shows the fractional yield change relative to the unadapted crop with the boxplots showing the range across the 6 member GCM-RCM ensemble. The pairs of boxes show the relative change in yield for the adaptation method in the historic climate (left) and the future climate (right).

# Projected changes in crop yield mean and variability over West Africa in a world 1.5 K warmer than the pre-industrial

**Abstract.** The ability of a ~~country or~~ region to feed itself in the upcoming decades is ~~a question of importance. The population in West Africa an important question.~~ The West African population is expected to increase significantly in the next 30 years. The responses of ~~food~~ crops to short term climate change is ~~therefore~~ critical to the population ~~at large~~ and the decision makers tasked with ~~providing food for their people.~~ food security. This leads to a three questions, How will crop yields change in the near future? What influence will climate change have on crop failures? Which adaptation methods should be employed to ameliorate undesirable changes?

An ensemble of near term climate projections are used to simulate maize, millet and sorghum in West Africa in the recent historic ~~and (1986-2005) and a~~ near term future ~~where global temperatures are 1.5 K above pre-industrial to assess the change in yield, yield variability and crop failure rate.~~ Four crop models were used to simulate maize, millet and sorghum in West Africa in the historic and future climates.

~~The mean yields are not expected to alter significantly, while there is an increase in inter-annual variability. Across the majority of West Africa the maize, millet and sorghum yields are shown to fall. In the regions where yields increase the variability also increases.~~ This increase in variability increases the likelihood of crop failures, which are defined as yield negative anomalies beyond one standard deviation during ~~a period of 20 years~~ the historic period. The increasing variability increases the frequency ~~and intensity~~ of crop failures across West Africa. The ~~mean return frequency between mild maize crop failures from process based crop models increases from once every 6.8 years to once every 4.5 years. The mean return time frequency for severe crop failures (beyond 1.5 standard deviations) also almost doubles from once every 16.5 years to once every 8.5 years.~~ return time of crop failures falls from 8.8, 9.7 and 10.1 years to 5.2, 6.3 and 5.8 years for maize, millet and sorghum respectively.

~~Two adaptation responses to climate change, the~~ The adoption of heat-resistant cultivars and the use of captured rainwater have been investigated using one crop model ~~in as~~ an idealised sensitivity test. The generalised adoption of a cultivar resistant to high temperature stress during flowering is shown to be more beneficial than using rainwater harvesting ~~by both increasing yields and the return frequency of crop failures.~~

## 1 Introduction

The densely populated region of West Africa has been identified as a region vulnerable to climate change impacts, from shifts in the monsoon system to desertification. The global climate is projected to pass 1.5 K above the pre-industrial control in the coming decades. ~~The arrival and strength of the West African monsoon is a key component of the cropping system as it provides much of the water used in the growing season. The uncertainty in how the monsoon will respond to climate change is therefore of high importance, which requires the use of more than one climate model when studying impacts.~~ (Kirtman et al., 2013). To maintain current levels of food intake the crop yields in West Africa will need to increase in step with the increasing population. All countries within West Africa are currently net importers of cereals indicating that their current production is insufficient to meet demand (FAOSTAT, 2014). The existing trends in African agriculture are not sufficient to provide this yield increase and shortages are therefore expected without the adverse effects of climate change (Ray et al., 2013; Gerland et al., 2014).

The changes to the global climate will have local implications on the growing conditions for crops. The primary source of water for West African crops is the West African monsoon. Studies have shown that the monsoon may start later in the year in West Africa under climate change, this in turn exposes the crops to the summer months when temperatures are higher (Biasutti and Sobel, 2009; Sultan et al., 2014).

Temperatures and rainfall are not the only drivers of crop yield that are expected to change; there are also possible changes in fertiliser deployment ~~and~~ thus nutrient availability (Lassaletta et al., 2014) ~~and~~ as well as farmers adaptation, e.g. through irrigation ~~of planting heat or~~ (Rockström and Falkenmark, 2000) ~~or planting heat and~~ drought resistant varieties in the case of dryer and warmer conditions. ~~Another~~ (Guan et al., 2017).

A factor is the increase in ambient carbon dioxide concentrations and therefore the potential carbon dioxide fertilisation of yields (Berg et al., 2013). This is primarily for C3 plants, the carboxylation of C4 plants is insensitive to carbon dioxide but carbon dioxide impacts maize development through stomatal closure and soil moisture conservation (Leakey, 2009).

~~To maintain current levels of food intake the crop yields in West Africa will need increase in step with the increasing population. However current trends in African agriculture are not sufficient to provide this yield increase and shortages are therefore to be expected even without the adverse effects of climate change (Ray et al., 2013).~~

There have been multiple studies investigating the future of maize, millet and sorghum yields in West Africa. ~~In most cases the crop yields are expected to decrease with climate change and that several growing regions may no longer be viable in the upcoming decades (Jones and Thornton, 2003).~~ A meta-analysis of 52 studies for several crops ~~shows reductions without adaptation show reductions by the 2050s,~~ in African yield of 5%, 10% and 15% for maize, millet and sorghum respectively (Knox et al., 2012).

The reduction in yields in Africa under climate change is further supported by the meta-analysis in Roudier et al. (2011) where multiple crops were shown to experience decreases in yield. ~~One process which increases yield is the~~ The meta-analysis in Roudier et al. (2011) used a number of climate scenarios including A1B, A2 and B1 from CMIP3 (Meehl et al., 2007).

with time horizons varying from 2025-2085, the majority of the publications analysed did not study adaptation methods. The results in Roudier et al. (2011) investigate the importance of the carbon dioxide fertilisation effect, ~~however~~ which was found to ameliorate some of the yield losses attributed to climate change. However it has also been shown the nutritional quality of the resultant crops is lower than in an atmosphere with current carbon dioxide concentrations (Roudier et al., 2011).

5 Much of the area currently used to grow maize in West Africa is also ~~predicted~~ projected to be unsuitable in the long term, ~~with~~. With a future climate based on RCP8.5 only 59.8% of the currently cultivated area predicted to be viable in ~~2100~~. 2100 (Rippke et al., 2016). Of the lost cultivated area, 40% can be used to grow sorghum or millets which are hardier to heat and drought stresses, however the remaining 60% has no suitable alternative (Rippke et al., 2016). The millet and sorghum growing areas however are not predicted to suffer as much as maize. Many of the above mentioned studies use climate projections that

10 find high warming levels at the end of the century.

The expected change in yield for maize was also calculated as part of a meta analysis where the response of maize to increasing temperatures with and without adaptation methods was investigated. The temperature changes were locally analysed and grouped independent of carbon dioxide fertilisation of global climate conditions. Tropical maize was found to experience a decline in yields as temperatures increase for both studies with and without adaptation (Challinor et al., 2014). There are multiple potential adaptation methods to ameliorate the impacts of climate change, a non-exhaustive list contains, intercropping,

15 changing the variety or species grown, use of fertilisers and crop rotation to replenish nutrients in the soil.

Several adaptation methods for sorghum were investigated in Guan et al. (2017) using two crop models for a future climate period of 2031-2060 under a RCP8.5 climate. The proposed adaptation methods included changing the planting date, rainwater capture and re-use and increasing resilience to high temperature stress during flowering amongst others. The results

20 in Guan et al. (2017) show that growing varieties with high temperature stress resistance during flowering is of more benefit in the future climate than rainwater harvesting. Sorghum yields are expected to decrease with climate change ~~and~~ based on simulations using data from RCP8.5 and between 2031-2060, while carbon dioxide fertilisation will ameliorate some of the losses, it will not eliminate them (Sultan et al., 2014). Lastly, for millet a model analysis produced an expected reduction in yields of 6% ~~across two~~ by 2070-2099 when compared with 1970-1999 across the A1B and A2 scenarios from

25 CMIP3 (Berg et al., 2013).

In this paper we use four crop models simulating three crops and driven by meteorological outputs from several regional climate models. Three C4 crops have been selected for this analysis; maize, sorghum and millet. They are a staple foods over much of West Africa and an important source of many nutrients. The aim of this paper is to ~~identify and quantify some of the sources of uncertainty in the West African agricultural system~~ produce probabilistic projections of West African crop yields

30 as the global climate passes 1.5 K above the pre-industrial control. This study makes use of newly available input data from CORDEX-Africa to differentiate from previous works. There are several possible responses to the increasing temperatures and altered precipitation regimes: these include modifying the planting window, using a new variety of a crop or changing the crop entirely. ~~The use of two~~ Two adaptation methods to mitigate the impacts of climate change has been investigated. These methods include an idealised crop which is resistant to heat stress during flowering and rainwater harvesting. A global

35 temperature increase of 1.5 K is drawing closer, with annual average carbon dioxide levels above 400 ppm in 2016.

## 2 Methods

### 2.1 Meteorological data

The input data for the crop models in this study was provided as part of the CORDEX-Africa project (Nikulin et al., 2012). CORDEX-Africa uses a selection of CMIP5 Global Climate Models (GCMs) to drive a number of Regional Climate Models (RCMs). The simulations used in this study are based on CMIP5 simulations of a high emission, low adaptation future climate where the radiative forcing at the end of the 21<sup>st</sup> century is +8.5 Wm<sup>-2</sup>, (RCP8.5) (Taylor et al., 2011; Meinshausen et al., 2011). The outputs from CORDEX-Africa were bias corrected as part of the HELIX project using multisegment statistical bias correction (Grillakis et al., 2013; Papadimitriou et al., 2015). The observations used to bias correct the CORDEX-Africa simulations was the WATCH-Forcing-Data-ERA-Interim: WFDEI (Weedon et al., 2014) record. The bias corrected CORDEX-Africa data was provided at a horizontal resolution of 0.44° and at a temporal resolution of one day. The multisegment approach of the bias correction will adjust the simulated variability to closely match the observed variability and in doing so removes a number of drizzle events from the record and increases the intensity of wetter events to match the observations (Papadimitriou et al., 2015).

The CORDEX-Africa simulations were found to perform well at replicating the large scale features of the West African climate including the inter annual variability in precipitation (Diaconescu et al., 2015). The precipitation in West Africa is primarily driven by the north-south motion of the monsoon (Nikulin et al., 2012). The CORDEX-Africa models were found to contain biases despite their good performance and therefore bias corrected model output were selected for further analysis (Gbobaniyi et al., 2015).

An ensemble of 10 GCMs and four RCMs were used as inputs to crop models and a total of 16 GCM-RCM combinations were utilised. None of the GCMs were used to drive all of the RCMs and of the RCMs, only RCA4 was used with every GCM. A table of the GCM-RCM combinations used is shown in Table 1. The control time slice for the experiment was 1986-2005 corresponding to the final 20 years of the CMIP5 historic simulations. The future time slice was taken as the 30 year period where the global average temperature was closest to 1.5 K above the pre-industrial control of 1870-1899. The time slices used for this experiment and the mean time slices weighted by both GCMs and RCMs are shown in Table 2. The GCM and RCM weighted mean time slices are within a year of each other at 2011-2040 and 2010-2039 respectively. The crop models that simulate carbon dioxide fertilisation also use the carbon dioxide concentrations as inputs for the future climate scenarios reached by each GCM when warming reaches 1.5 K. Thus, because of different transient climate responses of the GCMs, the crop models are exposed to a different carbon dioxide concentrations for each GCM climate forcing. Our choice of not normalizing the carbon dioxide levels for simulating crop yields is justified because we want to capture the full uncertainty of West African yield responses to both regional climate and global carbon dioxide conditions in a 1.5K warmer world.

### 2.2 Crop models

Four different crop models were used in this study, the Global Large Area Model for annual crops (GLAM) (Challinor et al., 2004), ORCHIDEE-Crop (Wu et al., 2016) which is the crop specific version of the ORganizing Carbon and Hydrology in

Dynamic Ecosystems (ORCHIDEE) land surface model (Krinner et al., 2005), System of Agroclimatological Regional Risk Analysis Version H (~~Sarra-H~~SARRA-H) (Kouressy et al., 2008) and a series of generalised linear models (Lobell and Burke, 2010). The planting and harvest dates for the crop models were determined using data generated as part of the Global Gridded Crop Model Intercomparison project (Elliott et al., 2015).

### 5 2.2.1 GLAM

GLAM is the Global Large Area Model for annual crops (Challinor et al., 2004), it is a process based crop model that simulates the growth of a crop on the scale of grid cells used in climate models (Challinor et al., 2004) (Parkes et al., 2015). GLAM uses four meteorological inputs: maximum and minimum daily temperatures, downwelling shortwave radiation and precipitation, all at the surface. GLAM used the maize yield data as an input, along with soil quantities taken from the Digital Soil Map of the World using the approach described in Vermeulen et al. (2013). GLAM uses an intelligent planting system to wait for soil moisture to reach a pre-defined limit before planting occurs. The parameter set for maize used in this study is based on the one used in Vermeulen et al. (2013). The high temperature stress at flowering routine was enabled, if the maximum daily temperature is above 37 °C the yield is reduced, above 45 °C the yield is set to zero (Challinor et al., 2005, 2015). To test the importance of high temperature stress during flowering, this routine is disabled. The rainwater harvesting routine used in

10 GLAM stores any runoff from the top layer of the soil in a reservoir, the reservoir is tapped when the soil moisture falls below the wilting limit. The amount of water released from the reservoir is enough to bring the soil up to 80% of the drained upper limit or the totality of the water stored. GLAM does not have a parameter set for sorghum or millet and therefore was not used to simulate those crops. The carbon dioxide fertilisation effect is simulated by increasing the transpiration efficiency of the crop, this is based on the mean carbon dioxide concentration for the simulated time period.

### 20 2.2.2 ORCHIDEE-Crop

ORCHIDEE-Crop is a land surface crop model, based on the generic vegetation model ORCHIDEE (Krinner et al., 2005), simulating carbon, water and energy fluxes (e.g. photosynthesis, respiration and evapotranspiration) and modules specifically designed to represent crop processes. The version of ORCHIDEE-Crop used in this study includes crop phenology module (Wu et al., 2016) and crop management modules (Wang et al., in prep), which has also submitted results for global gridded crop model intercomparison (Müller et al., 2016).

25 ORCHIDEE-Crop calculates thermal unit accumulation, photosynthesis and energy exchange on a half-hourly time step, while leaf area dynamics, carbon allocation and biomass and soil organic carbon change are simulated on a daily time step. The daily climate variables driving the model includes: maximum and minimum daily temperatures, downwelling shortwave and longwave radiation, surface pressure, wind speed and precipitation. The parameter set of maize was tested against a field experiment site in Ghana (Larvor, 2016). ORCHIDEE-Crop like GLAM does not have a parameter set for sorghum or millet

30 and was therefore not used to simulate those crops.

### 2.2.3 SARRA-H

SARRA-H (System for Regional Analysis of Agro-Climatic Risks), developed by the CIRAD, is a simple deterministic crop model for cereals operating at daily time steps (Dingkuhn et al., 2003; Baron et al., 2005; Kouressy et al., 2008) that simulates the growth of a crop on an adaptive scale of grid cells depending on the input data for Sorghum (90, 120 days or photoperiodic), Millet (90, 120 days or photoperiodic) and Maize (90 or 120 days). The performance in the analysis of climate impacts on tropical cereals is good (Mishra et al., 2008; Oettli et al., 2011). The yields are simulated under water-limited conditions by simulating the soil water balance, potential and actual evapotranspiration, phenology, potential and water-limited carbon assimilation, and biomass partitioning (see (Kouressy et al., 2008) for a detailed review of model concepts). The carbon dioxide fertilisation effect is not yet simulated. The optimum temperature is between 34 and 36°C and the limit temperature is between 44 and 46°C following the crop species. SARRA-H model does not explicitly simulate the effects of fertilizer, manure application, or residue on crop yields but reproduce different level of fertility (F1=>F4). The ratio between F1 to F4 rate is calibrated with a field survey in Burkina Faso. For the sowing it starts when plant-available soil moisture is greater than 8 mm at the end of the day and after the date determined by krigged field farmers survey. The establishment of the crop is monitored during the followed 20 days and if the condition is not correct during this period, the juvenile crop died and a re-sowing is automatically done. SARRA-H (Sultan et al., 2014) SARRA-H uses five daily meteorological inputs: maximum and minimum temperatures, downwelling shortwave radiation, precipitation and PET (Hargreaves formula), all at the surface. Others inputs are also used: soil depth and soil water holding capacity, and sowing density and depth.

#### 2.2.4 Linear models

The linear models use a design that has been used in several previous studies Estes et al. (2013); Lobell and Burke (2010); Wang et al. (2016). The models in this study use the robust linear fitting tools in MATLAB (Holland and Welsch, 1977) that are less sensitive to outliers than least squares fitting. The input data for the model have been polynomially detrended before fitting and the log of the yield was taken, this means the models produce relative changes in yield instead of absolute ones. The polynomial detrending used in the models is a two degree polynomial solved for each grid cell. The models solve the equation shown in Eqn 1 where a, b and c are constants for each grid cell and T and P are the seasonal mean temperature and total precipitation respectively.

$$Y_{it} = a_i + b_i T_{it} + c_i P_{it} \quad (1)$$

#### 2.2.5 Differences in the crop models

Both GLAM and ORCHIDEE-Crop were used to simulate maize, ~~Sarra-H~~ SARRA-H and the generalised linear models were used to simulate maize, sorghum and millet. ~~Descriptions of each crop model can be found in the Supplemental material.~~ GLAM and ORCHIDEE-Crop both respond to carbon dioxide fertilisation and ORCHIDEE-Crop has nitrogen fertiliser inputs as part of the simulated crop growth. The crop models all simulate crops based on a single planting and harvest without multicropping. GLAM and the linear models use observational yield as an input, in both cases the input yield is detrended using a two degree polynomial before use. This detrending removes consistent trends such as management changes and technological

improvements. GLAM unlike the other models was calibrated specifically for these simulations whereas ORCHIDEE-Crop and SARRA-H used pre defined parameter sets. The SARRA-H parameters were based on a study area in Burkina Faso. The process based models are time dependent and respond to the arrival of the monsoon, the linear models however only use the seasonal total precipitation. Linear models suffer with reduced accuracy outside the parameters space used to train them. In the short term linear models are not notably worse than process based models (Lobell and Asseng, 2017).

### 2.3 Agronomic data

The crop model's output were all analysed against their ability to reproduce observed crop yields and variability. The gridded input crop data for maize was taken from a dataset built from satellite observations combined with yields reported by the Food and Agriculture Organization of the United Nations (FAO) (FAOSTAT, 2014; Iizumi et al., 2014; Iizumi and Ramankutty, 2016). The millet and sorghum data were country level data from the Food and Agriculture Organization of the United Nations (FAO) (FAOSTAT, 2014). The cultivated areas for maize, millet and sorghum were defined by regriding the results from Monfreda et al. (2008) on the meteorological grid. To prevent the results being swamped by signals from grid cells with low cultivated area (Challinor et al., 2015), any grid cell with less than 1% coverage of each crop type of interest was eliminated.

## 3 Results

### 3.1 Crop model results

The four crop models were driven using the outputs of the four bias corrected CORDEX-Africa RCM simulations as listed in table 1. The CORDEX-Africa simulations were driven by ten GCMs as part of CMIP5. We present the first use of these data for a specific warming level of 1.5 K above the pre-industrial control. An annotated map of the analysed area is shown in SI Figure 1.

The results in Figures ??, ?? Figure 1 show the multi-model mean maize yield and yield interannual variability (hereafter IAV) respectively. The + and · symbols show grid cells where three of the four crop models agree with the sign of the response for the multi-model GCM-RCM mean, where + shows an increase and · shows a decrease. The model agreement is high in Côte d'Ivoire and Ghana but there is a spread of positive and negative impacts across Nigeria. The potential increases in yield in Côte d'Ivoire and Nigeria are also associated with to-increases in IAVs as shown in Figure ??. The millet results are shown in SI Figures 1 and 2 Figure 2 where a dipole can be seen in the yield response, the yield increases in northern Nigeria and southern Niger, however to the West in Burkina Faso and Mali there is a decrease in yields. The dipole is not as significant in the IAV results with increases in IAV in Niger, Nigeria and Burkina Faso. The IAV is reduced in Mali along with the yield. The stippled Sorghum results (SI Figures 3 and 4 Figure 3) present a smaller dipole effect that has positive yield change in Niger and a negative yield change over much of West Africa. Where the yield increases in Niger the IAV also increases which is expected to cause problems for food security.

The multimodel ensemble mean yields for the control and future time slices are calculated for each crop model and plotted against the observations in Figure ???. Of the shown in Tables 3, 4 and 5. For each yield value, the results are shown with the inter annual variability (IAV) in the yield as the first uncertainty and the model spread as the second uncertainty. The observations are shown with a single uncertainty as they have no model spread. The results in Tables 3, 4 and 5 show that the IAV is larger than the model spread for all crop models except the linear models. The ratio for the IAV in GLAM is much larger than for all other models, this is due to the simulations for the historical period in GLAM being calibrated on a per model basis and therefore having a very low model spread.

For maize (Table 3), of the process based models GLAM and Sarra-H-SARRA-H are closest to the observed yields whereas ORCHIDEE-Crop is further away. The linear models by design match the observed yields. The future climate responses for GLAM and Sarra-H-SARRA-H are limited however ORCHIDEE-Crop shows a strong reduction in yields. Sarra-H-SARRA-H and the linear models show an increase in yields at +1.5 K. The control simulation has temperatures that are 0.7 K above the pre-industrial control, therefore the temperature difference experienced by the crops is 0.8 K. The maize yield reductions are less than  $2-10 \pm 709 \pm 91$  kg/ha for GLAM,  $84-95 \pm 185 \pm 51$  kg/ha for ORCHIDEE, whereas Sarra-H-ORCHIDEE-Crop, whereas SARRA-H increases by around  $20-28 \pm 708 \pm 243$  kg/ha and the linear models increase by  $62-40 \pm 127 \pm 191$  kg/ha. In percentage terms these are less than 1.5% for GLAM, 5.7% for ORCHIDEE, 6.6% for ORCHIDEE-Crop and increases of 1.6% for Sarra-H and 5.3-2.2% for SARRA-H and 3.8% for the linear models. The responses for most models-

ORCHIDEE-Crop and GLAM simulate responses to carbon dioxide fertilisation. Both models project a small reduction in yield in future climates, the magnitude of which has been reduced by the increase in yield from carbon dioxide fertilisation. Carbon dioxide fertilisation increases the yield when the crop is limited by carbon dioxide. If the crop is water limited then the carbon dioxide fertilisation will have a smaller effect on yield. The yield losses in GLAM and ORCHIDEE-Crop are smaller than those found in the meta-analysis the mean reported in the meta-analysis by Knox et al. (2012), however this study is not projected as far into the future. The four different model results presented are-. The Knox et al. (2012) results are for crops in the 2050s and therefore our results are expected to be smaller as they are for a closer time horizon. A second meta-analysis by Challinor et al. (2014) presents results by temperature change, our results at 1.5 K are within the range of results from Challinor et al. (2014) found in their analysis.

The multimodel ensemble yield results contain two sources of uncertainty, the inter-annual variability (IAV)-IAV and the variability across the meteorological input datasets. The results for the IAV are shown in Figures ???. The results in Figure ?? in Table 3 show that ORCHIDEE-Crop has the most skill in reproducing the observed IAV followed by the linear models. Both GLAM and Sarra-H-SARRA-H overestimate the IAV for maize. Despite these differences, the IAV increases for all models in the future climate scenario. For the process based models the IAV is significantly larger than the variability resulting from differences in input meteorological data. Both GLAM and ORCHIDEE-Crop show little variability across the input data in the control scenario. For ORCHIDEE-Crop, GLAM and the linear models the variability increases in the future climate, this is in contrast to the results in Sarra-H-SARRA-H.

Figures ?? and ?? show Figure 4 shows the mild and severe crop failure rate for maize in the control (20 years) and future (30 years) climate scenarios. A mild crop failure is one standard deviation below the observed yield for that grid cell, a severe crop

failure is 1.5 standard deviations below the ~~observed-simulated~~ yield for that grid cell ~~-in the historic simulation, the historic simulation is used to prevent model bias in yield from dominating the variability signal (Parkes et al., 2015). The number of crop failures is recorded for each grid cell and the total across the domain is calculated. The total number of simulations for a crop model is the number of analysed grid cells multiplied by the number of years of simulation. The total number of crop failures is divided by the total number of simulations to give a fractional number of crop failures, this is the crop failure rate with units of failures per grid cell per year. The inverse of the crop failure rate is the mean return time for a crop failure.~~ GLAM slightly underestimates the mild crop failure rate, whereas ORCHIDEE-Crop and ~~Sarra-H-SARRA-H~~ overestimate slightly. The differences however are minor in comparison to those found in the linear models. The severity of the change in mild crop failure rate varies across the process based models but the signal is consistent, at 1.5 K above pre-industrial there is an expectation of more crop failures. ORCHIDEE-Crop is particularly pessimistic with the return time between crop failures falling from 6.1 years to 2.5 years per grid cell. For severe crop failures the process based models are again more realistic than the linear models. The future climate results show an increase in severe crop failures, with ORCHIDEE-Crop again showing the strongest response.

The millet and sorghum ~~results are shown in SI Figures 5–12. The millet and sorghum~~ analyses for three varieties simulated by the ~~Sarra-H-SARRA-H~~ model and the linear models. The linear models are more able to predict the observed yield and inter annual variability than ~~Sarra-H-SARRA-H~~ for millet and sorghum (~~SI Figures 5, 6, 9 and 10 Tables 4 and 4~~). In the millet simulations the linear models are close to the observed yield whereas the ~~Sarra-H-SARRA-H~~ varieties are spread above and below the observations. ~~Of the Sarra-H varieties the~~ ~~The yield changes are negative for the linear models and the SARRA-H 90 day variety. The three variants of SARRA-H like the linear models underestimate the frequency of crop failures in the control (Figure 4), this is most likely a result of overestimating the IAV and therefore giving a too low limit for a crop failure. The expected return time for a crop failure in the observations is 5.3 years which is shorter than the 8.0, 7.4 and 7.8 years from SARRA-H varieties (90 day, 120 day PP sensitive) and drastically difference from the 41.1 years in the linear models. For severe crop failures the models perform worse and the return time of 15 years is increased to 21 in the SARRA-H PP day variety which is the best of the models. The future crop failure return time is consistently shorter than the historic indicating more frequent crop failures.~~

~~For Sorghum, the SARRA-H 90 day cultivar is most capable of reproducing the observed sorghum yields yield, however the yields are still about 2015% too low. The response of the 90 day cultivar to the future climate are consistent with the simulations in Sultan et al. (2014).~~

~~The three variants of Sarra-H like the linear models underestimate the frequency of crop failures in the control (SI Figures 7, 8, 11 and 12). Across all three crops and all models there is an increase in As SARRA-H was used for both millet and sorghum the results are similar with the overestimate of the IAV causing an underestimate of the crop failure rate in the future climate when compared with the historic climate.~~

~~With ensembles of input data it is possible to calculate two different uncertainty values, the IAV and the spread across the ensemble. The ratio of IAV to input data spread is shown in SI Figures 13-15 for maize, millet and sorghum. The results show that the IAV is always larger than the model spread. The ratio for the IAV in GLAM is much larger than for all other models,~~

~~this is due to the simulations in for the historical period in GLAM being calibrated on a per model basis and therefore having a very low model spread. The return time of a crop failure is 5.6 years in the observations but the SARRA-H varieties (90 day, 120 day PP sensitive) find 7.8, 8.6 and 7.9 years and the linear models produce a return time of 35.5 years. The same features are found for the severe crop failures where the return time is overestimated in all models.~~

- 5 The results in Tables 6, 7, 8 show the change in national yields for each model and the multi-model mean. ~~The per model production changes are averaged and shown in the rightmost columns of the tables.~~ Countries with fewer than 10 grid cells analysed have been omitted from the tables. The results for maize show a spread in expected yield changes by nation, with ~~the Cameroon and Côte d'Ivoire experiencing an increase in yield and Ghana showing a decrease. Nigerian yields are uncertain and the average is a very small change.~~ There are yield reductions in Benin, Burkina Faso, Ghana, Mali and Senegal with
- 10 ~~limited changes in Nigeria and Togo.~~ ORCHIDEE-Crop ~~finds a yield reduction in all three countries, whereas GLAM, Sarra-H and the Linear models are only negative for one country~~ dominates the production change with a large negative change to a highly productive nations including Ghana and Nigeria. Only Benin, Burkina Faso and Senegal are projected to suffer yield reductions in all four crop models for maize. In the future climate simulations at the 1.5 K warming level Burkina Faso, ~~Mali, and Senegal all and Mali~~ suffer a more than 5% loss in millet yields while Niger ~~is predicted and Nigeria are projected~~ to
- 15 experience an increase of ~~3.2%, 4.2% and 4.2%.~~ These yield changes result in an increase in production that is dominated by Nigeria, however production falls significantly for Burkina Faso, Mali and Senegal. The sorghum results (Table 8) nearly always show a yield reduction with climate change with the exception of Niger which has a ~~small~~ yield increase. The sorghum results show a 10% yield reduction for Burkina Faso, Mali and Senegal. ~~The negative trends in the yields are also present in the production of sorghum in West Africa with Niger being the only exception.~~
- 20 The results in Figure 5 show the responses of the maize yield to changes in precipitation and temperature change for four crop models. To highlight the responses of precipitation changes between -50% and +50% the x-axis of the left figure is truncated, a full version of the figure is shown in SI Figure 2. The maize yields in all models show an increase in yield with increasing precipitation. A negative trend is also present with increasing temperatures. The differences between the crop models can be seen in these figures. The results in ORCHIDEE-Crop show less variability than SARRA-H, GLAM or the Linear models
- 25 and have a strong negative yield response for a limited temperature change. The temperature change experienced by the crops simulated in GLAM covers a larger range than the other models and the positive relationship between precipitation and yield is also shown. Water scarcity has a smaller impact on SARRA-H and the Linear models than in GLAM or ORCHIDEE-Crop and the SARRA-H results do not show a strong negative response to higher temperatures.

### 3.2 Adaptation results

- 30 In one of the four crop models (GLAM) simulations of two idealised adaptation methods were performed. There were three experiments, crops with a resistance to high temperature stress during flowering, crops grown with rainwater harvesting and crops resistant to high temperature stress with rainwater harvesting deployed. To simulate ~~a crop resistant to high temperature stress resistance the~~ GLAM is rerun with the high temperature stress routine disabled, a description of high temperature stress in flowering is found in Challinor et al. (2005). ~~Disabling the high temperature stress routine produces an unphysical crop~~

and is used to give guidance on the importance of high temperature stress. The rainwater harvesting system collects runoff from the crop and stores it with 50% efficiency, the water is deployed if the soil moisture falls below the wilting limit for the crop. The adaptation methods are simulated in both the control climate and the future climate ~~using the approach described in Lobell (2014).~~

5 The adaptation results for GLAM (Figure 6) show that rainwater harvesting is provides a smaller increase in yields in the global 1.5 K warmer climate than in the historic climate. The results for the return time between crop failures show an improvement in the control climate that is greater than in the future climate. In contrast the high temperature stress resistant crops show a benefit in both cases and a larger benefit in future climates. The return time between crop failures also increase more in future climates. However when combined with rainwater harvesting, high temperature stress resistance has a smaller  
10 relative improvement than when it is deployed in isolation. The maize results from GLAM presented here agree show similar responses to the sorghum results in Guan et al. (2017) where high temperature stress resistance is more important than rainwater harvesting. This result needs to be considered alongside the results in Figure 5 which show a strong negative precipitation response in GLAM, indicating that the rainwater harvesting routine, while providing some extra water does not provide enough to counteract the precipitation changes in the future simulations.

#### 15 4 Discussion

The results in ~~Figure ??, SI Figures 5 and 9~~ Figures 1, 2 and 3, show that as the global climate warms through 1.5 K the yield response is uncertain. For maize, GLAM and ORCHIDEE-Crop simulate a reduction in yields. Across all crops and models the largest reduction is 16.5% for ~~Sarra-H~~ SARRA-H 90 day sorghum. The largest increase is found for the linear models and is ~~5.3% for maize~~ 4.2% for millet. This range of results is within the range found for tropical maize in Challinor et al. (2014).

20 ORCHIDEE-Crop ~~is successful at replicating replicates~~ the observed IAV and ~~does not suffer from spread from the input data, however the mean yield results in contrast with the other process based models, GLAM and SARRA-H. The mean yields however~~ do show a significant bias. The ORCHIDEE-Crop results show the greatest increase in crop failure rate with crop failures occurring once every 2.5 years in the future climate scenarios. The crop failure rates for GLAM and ~~Sarra-H~~ SARRA-H are similar with future failures happening every 6 and 5 years respectively. The linear models consistently underestimate the  
25 crop failure rate and this is one of their weaknesses. The results in ~~Figures ?? and ??~~ Figure 4 show consistency across all three process based models and therefore should be treated with confidence.

The varieties of ~~Sarra-H~~ SARRA-H are unable to replicate the observed yields for the millet and sorghum analyses and mis-estimate the yield by several hundred kg/ha (~~SI Figures 5 and 9~~ Figures 2 and 3). The crop failure rate is defined by the model yield and the ~~Sarra-H~~ SARRA-H simulations all underestimate the crop failure rate. They do however all find a relative  
30 increase in crop failure rate in future climates for both millet and sorghum.

The differences in the crop models and inputs have an influence on the results. From Figure 1 GLAM shows a greater spread of yield change with climate change than the other models whereas ORCHIDEE-Crop and SARRA-H are more consistent under climate change. The yield changes in ORCHIDEE-Crop and GLAM are also influenced by the carbon dioxide

fertilisation effect and in its absence the projected yields are expected to be lower. The IAV results show greater spread in the linear models than the process based models, this is a result of the simple parameters in the linear models. The results in Figure 5 show that GLAM has a stronger negative response to precipitation loss than the other models. The temperature results for all models show a downward trend in yield with increasing temperatures. The lack of variability in the linear models is shown in Figure 4 where they consistently underestimate crop failure rates. ORCHIDEE-Crop has a smaller IAV than the other process based models which means the crop failure limit is much higher than in the other models. This results in ORCHIDEE-Crop finding a significant increase in the number of crop failures. As the ORCHIDEE-Crop IAV is closest to the observed IAV (Table 3), this indicates that GLAM and SARRA-H are likely to underestimate the number of future crop failures. For Figures 2 and 3 the country scale yields in the historic inputs can be clearly seen in the linear models as opposed to the spread of yield values in SARRA-H. As with SARRA-H, GLAM and the linear models in maize, the SARRA-H varieties and the linear models underestimate the variability and therefore the crop failure rate for both millet and sorghum.

The adaptation methods tested in GLAM for maize are shown in Figure 6 and show that rainwater harvesting is not an effective adaptation method. The higher rainfall in future climates reduces the likelihood of water limiting the crop growth. The high temperature stress adaptation is a more efficient adaptation and provides a benefit in the future climate. The combined HTS resistant and rainwater harvesting adapted crop is less of an adaptation than solely HTS resistant crop. Therefore in the case of limited resources it is better decision to explore HTS resistance than building systems to capture runoff, especially as the systems require substantial investment to construct and maintain.

The changes in national yields is a cause for concern as it is well documented that populations in West Africa are expected to increase quickly in the 21<sup>st</sup> century. Crop yields need to double by 2050 to feed the population (Ray et al., 2013), whereas the largest increase found in this study is ~~millet sorghum~~ in Niger at ~~+3.20%. The 8.84%~~, which if replicated across the entire region would be sufficient however it is in contrast to the falling yields found instead. The production changes show the importance of different growing areas, the lack of strong positive changes in yield across Sub-Saharan West Africa is a concern. The mean yield changes are not the only message, in many cases where the mean yield increase there is an accompanying increase in IAV. The increase in IAV means that yield are more uncertain and there is an increasingly likelihood of crop failures. The reductions in yields on national levels indicate a need for new breeds of crop or changing species entirely, however the rate of deployment of new breeds in Africa is slow (Challinor et al., 2016).

## 5 Conclusions

Four crop models of varying design and complexity have been used to project crop yields across West Africa for three crops as global temperatures reach 1.5 K above the pre-industrial levels. The crops models were driven by the outputs of four RCMs which were in turn driven by 10 GCMs. The crop models show differing levels of skill at reproducing the yield and variability found in the observed record. The process based models are able to predict the crop failure rate for maize with moderate skill. The varieties of crop simulated by ~~Sarra-H~~ SARRA-H for millet and sorghum are less able to replicate observations than the linear models, but they are more capable for the crop failures. This study is limited by the number of crop models used, in

particular only one process based model was used to millet and sorghum. The use of bias corrected RCMs to provide input data removes some of the problems associated with GCM data. The large size of the grid (50km) prevents the formation of true convective storms and therefore the intensity of the weather is likely to be underestimated (Garcia-Carreras et al., 2015).

5 The crop yields and percentage changes in yield were calculated for several West Africa countries. The yield changes are not consistent across national borders and some nations are expected to lose more than others. The yield gains predicted herein need to be considered as part of longer term trends that show severe yield reductions as the 21<sup>st</sup>21<sup>st</sup> century progresses (Challinor et al., 2014; Knox et al., 2012). As global temperatures approach 1.5 K above the pre-industrial levels, the knowledge of the most effective adaptation methods becomes critical and therefore it is of high importance to develop models capable of simulating them.

10 The results from this study show that for several crops the mean yield may not change much, however the increase in variability is likely to result in an increase in crop failures. The average crop yield responses are sometimes negative and none are positive enough to increase yields sufficiently to prevent food shortages.

*Data availability.* The input data for the crop models is part of the HELIX project and is currently under embargo. Upon the expiration of the embargo the data will be made available by the HELIX project. Contact information is at <https://www.helixclimate.eu/contact/>. The yield  
15 data output for the crop models can be found at <https://doi.pangaea.de/10.1594/PANGAEA.876579>

*Author contributions.* BP acquired the data and performed the simulations in GLAM, ORCHIDEE-Crop and the Linear models. DD ran the SARRA-H simulations. XW provided technical support for ORCHIDEE-Crop. All authors contributed to the manuscript.

*Competing interests.* The authors declare no competing interests.

*Acknowledgements.* This work received support from the European Commission's 7th Framework Programme (EU/FP7) under Grant  
20 Agreement 603864 (HELIX).

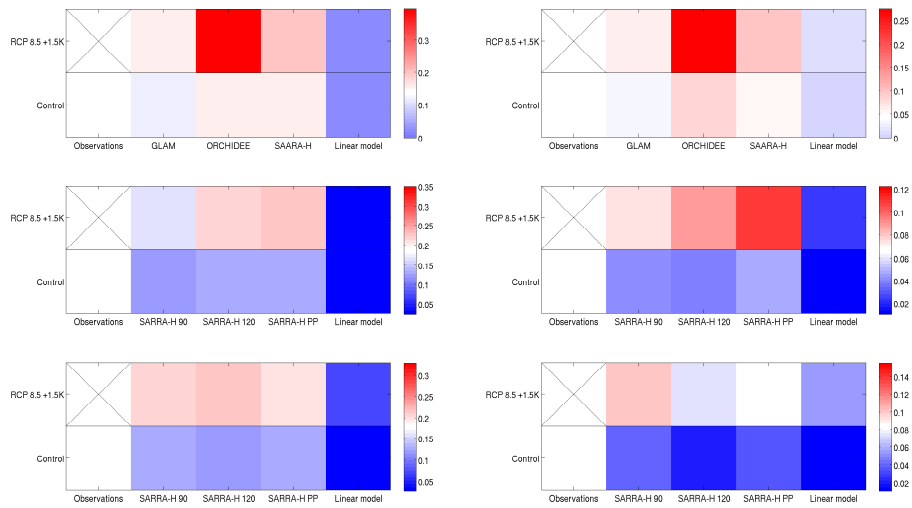

**Figure 1.** Multi-model mean change in maize yield and yield IAV between control the historic and future climates over West Africa in a world 1.5 K warmer than pre-industrial. Where The top left shows the change in yield where + indicates that in three crop models agree the change will be positive and · indicates that in three crop models agree the change will be negative. Sarra-H indicates The top right is the model simulating same as the 90-day variant top left except for IAV instead of maize yield. The units of the colour bar in the top plots is kg/ha. The bottom left shows the fractional change in yield against yield for all analysed grid cells. The bottom right shows the fractional change in yield IAV against yield for all analysed grid cells.

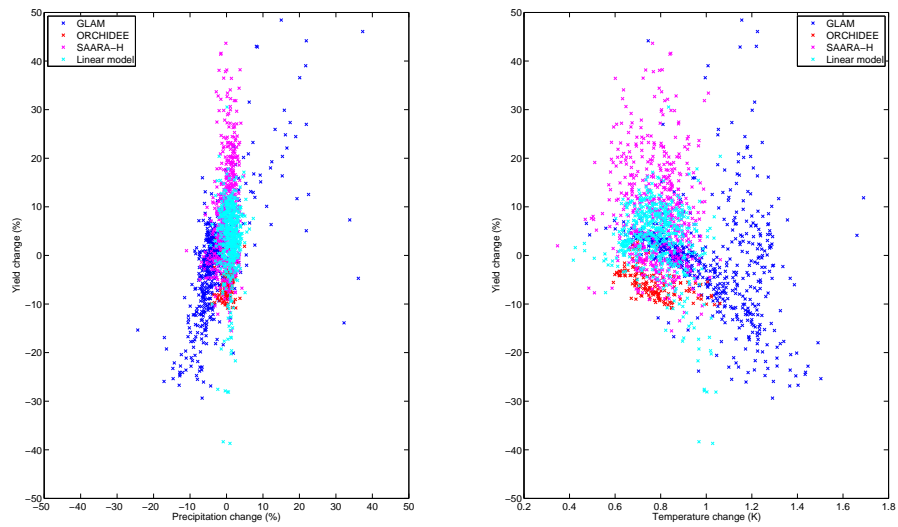

**Figure 2.** Multi-model mean change in maize-millet yield and yield IAV between control the historic and future climates over West Africa. The top left shows the change in a world 1.5 K warmer than pre-industrial. Where + indicates that in three crop models agree the change will be positive and · indicates that in three crop models agree the change will be negative. Sarra-H indicates the model simulating same as the 90-day variant top left except for IAV instead of maize yield. The units of the colour bar in the top plots is kg/ha. The bottom left shows the fractional change in yield against yield for all analysed grid cells. The bottom right shows the fractional change in yield IAV against yield for all analysed grid cells.

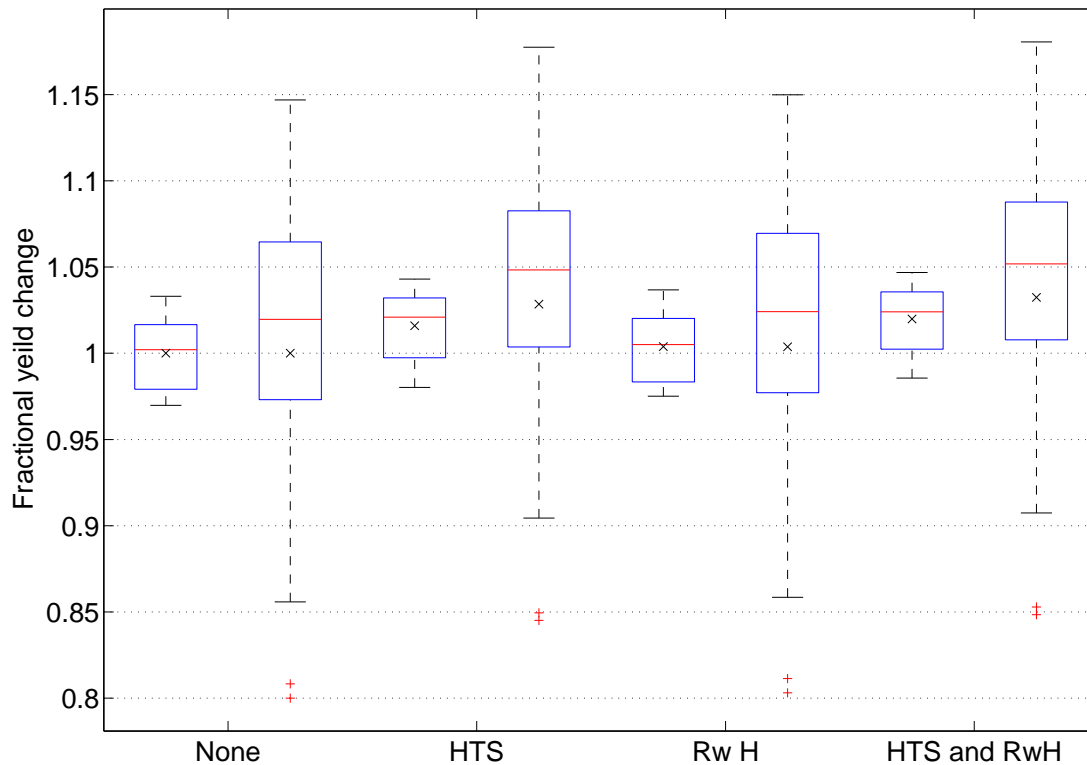

**Figure 3.** Heatmap of maize yields for four Change in sorghum yield and yield IAV between the historic and future climates. The top left shows the change in yield where + indicates that in three crop models for the control time period change will be positive and at 1.5 K indicates that in three crop models the change will be negative. The top right is the same as the top left except for IAV instead of yield. The units of the colour bar in the top plots is kg/ha. The bottom left shows the fractional change in yield against yield for all analysed grid cells. The bottom right shows the fractional change in yield IAV against yield for all analysed grid cells.

**Figure 4.** Heatmaps of inter-annual variability of maize yields—Mild (left) and severe (right) crops failures for four models for the control time period maize (top), millet (middle) and at 1.5K sorghum (bottom) in West Africa.

**Figure 5.** Heatmap of mild crop failure rate of Percentage maize yield change against precipitation (left) and temperature (right) for four crop models for. This figure has a restricted x-axis in the control time period precipitation plot to enhance the clarity of the results and at 1.5 K a full version is shown in SI Figure 2.

**Figure 6.** Heatmap Efficacy of severe adaptation methods for maize in GLAM. HTS is high temperature stress adapted crops, Rw H shows crops with rainwater harvesting, HTS and Rw H shows both adaptation methods in use. Each box shows the fractional yield change relative to the unadapted crop failure rate with the boxplots showing the range across the 6 member GCM-RCM ensemble. The pairs of maize boxes show the relative change in yield for four models for the control time period adaptation method in the historic climate (left) and at 1.5 K the future climate (right).

Efficacy of adaptation methods for maize in GLAM. Where circles show mean yield, crosses and stars show average number of years between mild and severe crop failures respectively. HTS is high temperature stress adapted crops, Rw H shows crops with rainwater harvesting, HTS & Rw H shows both adaptation methods in use.

**Table 1.** GCMs and RCMs where **X** indicates a RCM-GCM combination used in this study. The RCM description papers are as follows: RCA4 (Chylek et al., 2011), RACMO22T (van Meijgaard et al., 2008), HIRHAM5 (Christensen et al., 2006). The GCM description papers are as follows: CNRM-CM5 (Voltaire et al., 2013), CM5A-MR (Dufresne et al., 2013), CSIRO-Mk3.6.0 (Rotstayn et al., 2012), NOAA-GFDL-CM3 (Griffies et al., 2011), MOHC-HadGEM2-ES (Jones et al., 2011), ICHEC-EC-EARTH (Hazeleger et al., 2012), MIROC5 (Watanabe et al., 2010), MPI-ESM-LR (Raddatz et al., 2007), NorESM (Bentsen et al., 2013).
