Abstract. Climate oscillations are periodically fluctuating oceanic and atmospheric phenomena, which are related to variations in weather patterns and crop yields worldwide. In terms of crop production, the most widespread impacts have been observed for the El Niño Southern Oscillation (ENSO), which has been found to impact crop yields in all continents that produce crops, while two other climate oscillations - the Indian Ocean Dipole (IOD) and the North Atlantic Oscillation (NAO) - have been shown to impact crop production especially in Australia and Europe, respectively. In this study, we analyse the impacts of ENSO, IOD and NAO on the growing conditions of maize, rice, soybean and wheat at the global scale, by utilizing crop yield data from an ensemble of global gridded crop models simulated for a range of crop management scenarios. Our results show that simulated crop yield variability is correlated to climate oscillations to a wide extent (up to almost half of all maize and wheat harvested areas for ENSO) and in several important crop producing areas, e.g. in North America (ENSO, wheat), Australia (IOD & ENSO, wheat) and northern South America (ENSO, soybean). Further, our analyses show that higher sensitivity to these oscillations can be observed for rainfed, and fully fertilized scenarios, while the sensitivity tends to be lower if crops are fully irrigated. Since, the development of ENSO, IOD and NAO can be reliably forecasted in advance, a better understanding about the relationship between crop production and these climate oscillations can improve the resilience of the global food system to climate related shocks.

1 Introduction

Climate oscillations are periodically fluctuating oceanic and atmospheric phenomena, and they have been shown to impact hydroclimatological conditions (Dai et al. 1998, Hurrell et al. 2003, Saji and Yamagata 2003, Trenberth 1997, Ummenhofer et al. 2009, Ward et al. 2014) as well as crop productivity (Anderson et al. 2017, Ceglar et al. 2017, Heino et al. 2018, Iizumi et al. 2014, Yuan and Yamagata 2015) worldwide. The most notorious climate oscillation, the El Niño Southern Oscillation (ENSO), is most significant driver of global climate variability (Trenberth 1997), while two other prominent and widely studied climate oscillations, the Indian Ocean Dipole (IOD) (Saji et al. 1999), and the North Atlantic Oscillation (NAO) (Hurrell 1995), are also known to affect temperature and precipitation patterns around the globe (Hurrell et al. 2003, Saji and Yamagata 2003).

All of these three climate oscillations have been shown to significantly impact crop productivity in global (Heino et al. 2018, Iizumi et al. 2014) as well as regional (Anderson et al. 2017, Ceglar et al. 2017, Yuan and Yamagata 2015) studies. The IOD, for example, strongly affects Australia's drought patterns (Ummenhofer et al. 2009) and crop production (e.g. wheat (Yuan and Yamagata 2015)), while NAO has been shown to impact crop productivity particularly in Europe (Ceglar et al. 2017), but also in the Middle East, Northern Africa and some parts of Asia (Heino et al. 2018, Wang and You 2004). However, the largest fingerprint of these three oscillations is that of ENSO, which has been found to impact crop productivity in all continents that produce crops (Iizumi et al. 2014).

As the phase and development of ENSO, IOD and NAO can be forecasted from several months (IOD, NAO (Luo et al. 2008, Scaife et al. 2014)) potentially up to one year (ENSO (Luo et al., 2005, Ludescher et al. 2014)) in advance, considerable possibilities arise from understanding the impacts of these climate oscillations on crop production. If these impacts were better understood, it would allow national food agencies, international aid organizations, as well as food industries and farmers to prepare for varying crop development conditions. This would yield great benefits in increasing the resilience of the global food system to climate related shocks.

Until now, global scale studies about the relationship between crop production and climate oscillations have relied on individual satellite-based (Iizumi et al. 2014) or single-model simulated (Heino et al. 2018) crop yield estimates. The data produced and published in the global gridded crop model intercomparison (GGCMI) of the Agricultural Model Intercomparison and Improvement Project (AgMIP) now allows conducting assessments related to crop yield variability with an ensemble of models and a range of fertilizer use and irrigation set-ups (Elliott et al. 2015). Given the large variation in crop yield estimates across models (Müller et al. 2017, Rosenzweig et al. 2014), using an ensemble of models can allow for more robust estimates with better quantification of uncertainty in estimated yield impacts than using a single model.

By using the historical crop yield output derived from a multi-model ensemble of GGCMI, we aim to analyse the impacts of ENSO, NAO and IOD on maize, rice, soybean and wheat yields at the global scale. This extends previous studies, which are based on individual crop yield estimates (Heino et al. 2018, Iizumi et al. 2014) and have assessed the impacts of solely ENSO

(Iizumi et al. 2014) or the impacts of multiple oscillations on an aggregated crop productivity proxy (Heino et al. 2018). Further, since it is well known that agricultural management can have a major influence on climate induced crop yield variations (Challinor et al. 2014, Müller et al. 2018), we assess these impacts in different irrigation and fertilizer use scenarios. As a result, we are able to highlight potential management options to mitigate the impacts of these oscillations on crop production. In the Results and Interpretation section we also compare our results with previous work in order to provide a comprehensive overview of known phenomena while avoiding repetition.

2 Data and methods

2.1 Physically simulated crop yield data

Global data of physically simulated maize, rice, soybean and wheat yield (t ha^{-1}) were obtained for the global gridded crop models (GGCMs) included in the GGCM of AgMIP (Elliott et al. 2015). While most of the 12 models included here simulate the growth of all four target crops, a few simulate only some (Table 1): EPIC-TAMU (maize and wheat), pAPSIM (maize, soybean and wheat), and PEGASUS (maize, soybean and wheat). A recent study evaluated the performance of the models, included in the GGCM of AgMIP, in reproducing reported historical yield anomalies, and did not find any GGCM clearly superior to any other (Müller et al. 2017), thus highlighting the benefits of utilizing a model ensemble in yield variability assessments to account for uncertainty in individual model results.

Table 1. Crop yield data used in this study. ‘All’ refers to all of the crops included in this study, i.e. maize (M), rice (R), soybean (S) and wheat (W). Three model configurations were utilized: harmonized growing season and nutrient input (fullharm), harmonized growing season and no nutrient limitation (harm-suffN), and standard model assumptions (default). Details about the climate forcing data availability are given in the footnotes.

	Crops included for different model configurations			Model Reference	Data reference

5 Yield variability in the GGCMS included in GGCMI is mainly driven by weather circumstances and CO₂ concentration, while soil conditions and agricultural management practices are considered static (Müller et al. 2017). To account for varying assumptions of growing season and fertilizer use, in GGCMI, model simulations were conducted for three configurations:

standard model assumptions (default), harmonized growing season and nutrient input (fullharm), and harmonized growing season with no nutrient limitation (harm-suffN). In the harmonized model set-ups, crop planting and harvesting dates are based on literature, while fertilizer application rates are either unlimited (harm-suffN) or based on published data (fullharm). Further, all of the GGCM simulation results are provided separately for irrigated and rainfed conditions. In the irrigated simulation settings, no restrictions on water availability are considered (Müller et al. 2017). Two models included in the GGCM archive, PRYSBI2 and CLM-Crop, were excluded from this study because either the harmonization of growing season provided unreliable results (CLM-Crop) or the model does not distinguish between rainfed and irrigated crops (PRYSBI2).

The actual (literature based shares of rainfed and irrigated areas, see Sect. 2.3) cropping scenario, used in the main analyses, utilizes the fullharm set-up, and the harm-suffN setting for LPJ-GUESS and LPJmL, which do not consider nitrogen limitation and thus cannot harmonize on fertilizer settings (Table 2). For comparison, the sensitivity analysis for the actual cropping scenario was repeated with the default model set-up (see Supplement), while the harm-suffN scenario was used in assessing the impacts of the oscillations in fully fertilized conditions.

Table 2. The management scenarios used in this study. The actual set-up is used in the main analyses, while the fully irrigated, rainfed, fully fertilized, and the fully irrigated and fertilized management scenarios are used for comparing the impacts in different cropping systems.

Management scenario	Irrigated areas	Fertilizer use
Actual	Literature based	Literature based*
Fully irrigated	All areas irrigated	Literature based
Rainfed	No areas irrigated, all areas rainfed	Literature based
Fully fertilized	Literature based	Fully fertilized
Fully irrigated and fertilized	All areas irrigated	Fully fertilized

*) For LPJ-GUESS and LPJmL, limitations on fertilizer use are not considered. These models are excluded from the Actual scenario for the comparison with varying fertilizer use.

This study utilizes simulations driven with two historical meteorological forcing data sets (bias-corrected re-analysis weather data sets): AgMERRA (Ruane et al. 2015) and Princeton Global Forcing data set (Sheffield et al. 2006) (Table 1). AgMERRA was selected as the main climate input for this study, as a large number of GGCMs supplied data for this climate forcing data set, while the Princeton data was selected for reference due to its long timespan and previous use in a similar study (Heino et al. 2018). A detailed description of the GGCM modelling protocol can be found in Elliott et al. (2015).

2.2 Climate oscillation data

To represent the historical fluctuations of ENSO, IOD and NAO, the following indices were chosen: the Japan Meteorological Agency (JMA) SST Index (Florida State University 2015), the SST Dipole Mode Index (Japan Agency for Marine-Earth Science and Technology 2010, Saji et al. 1999), and Hurrell's North Atlantic Oscillation Index (primary component (PC)-based) (Hurrell 1995, National Center for Atmospheric Research 2015), respectively. These indices were selected because they are all well established and have already been used in several studies related to crop production (Heino et al. 2018, Kim and McCarl 2005, Yuan and Yamagata 2015). They were transformed to annual values by calculating the mean index for the months when the oscillations tend to have the strongest signal, according to existing sources, (i.e. December, January, February for ENSO (Trenberth 1997) and NAO (Hurrell et al. 2003); September, October and November for IOD (Saji et al. 1999)). This therefore only tests for relationships with a phase-locked measurement of the oscillation rather than investigating intra-annual temporal effects. Using seasonal or monthly data increases the number of significance tests for a given location and therefore the risk of false positives, and interpretation of results would require understanding of how climate oscillations, local weather conditions and yield are connected over time. Finally, in order to make the oscillation indices comparable with each other, each oscillation index time series was standardized (by subtracting the annual index values by their average and dividing with their standard deviation).

2.3 Crop yield data aggregation and de-trending

The gridded crop yields were allocated to oscillation specific annual yields based on the harvesting dates used in the harmonized GGCMI simulations. Hence, oscillation-specific "harvest years", which start from the first day that the respective oscillation index is calculated, are defined. For NAO and ENSO (oscillation index calculated for DJF), the harvest year is from December 1st to November 30th, while for IOD (calculated for SON) the harvest year is from 1st of September until end of August.

The crop yield data were aggregated spatially to the geographical scale of Food Producing Units (FPUs), which divide the world into 573 spatial units that are hybrids of river basins and administrative (economic) areas (Kummu et al. 2010). For the actual cropping scenario, rainfed and irrigated crop yields were combined by calculating the mean yield as the total production divided by the total harvested area across both cropping systems using literature based values about harvested area (Portmann et al. 2010). The aggregation for irrigated and rainfed scenarios was conducted similarly by dividing total production by harvested areas but assuming that all cropland is either irrigated or rainfed, respectively.

In order to extract the interannual variability of the crop yield data, they were de-trended. This was conducted by subtracting a five-year average (three-year average at both ends of the time series) yield from the annual yield values, similarly to several previously conducted studies about yield variability (Iizumi et al. 2014, Iizumi and Ramankutty 2016, Müller et al. 2017,

Müller et al. 2018). The anomalies were then divided by five-year (or three-year) averages to obtain proportional annual deviation from the normal values. The equation of the procedure is shown below:

$$\Delta Y_{f,s,m,c,t} = \frac{Y_{f,s,m,c,t} - \bar{Y}_{f,s,m,c,t}}{\bar{Y}_{f,s,m,c,t}} * 100, (1)$$

where $\Delta Y_{f,s,m,c,t}$ denotes relative yield anomaly for each FPU (f), scenario (s), model (m), crop (c) and year (t) compared to the average yield ($\bar{Y}_{f,s,m,c,t}$) for the rolling time window in question. The use of a shorter time window at the beginning and end of the yield time series allows longer de-trended time series, and it is assumed that it would rarely lead to errors about the sign of yield anomalies and thus the derived relationships between climate oscillation and yield anomalies. Other studies have tested other de-trending methods as well, but have found no major impact from the method selected (Iizumi et al. 2014, Iizumi and Ramankutty 2016, Müller et al. 2017).

10 2.4 Crop yield sensitivity to the oscillations

The sensitivity of actual crop yield to the oscillations was investigated using a linear regression model, with the oscillation indices as explanatory variable and the annual crop yield anomalies as dependent variable. In this linear regression model, the slope represents sensitivity. For the main analysis, a linear fit was calculated for each FPU using crop yield anomaly time series from all GCMs that simulate the crop in question with the AgMERRA climate input (N=216-297, depending on crop).

$$15 [S_{f,s,c,o} \ i_{f,s,c,o}] = (I_{o,t}^T I_{o,t})^{-1} I_{o,t}^T \Delta Y_{f,s,m,c,t}, (2)$$

where $S_{f,s,c,o}$ and $i_{f,s,c,o}$ are the slope (i.e. sensitivity) and intercept of the regression model for each FPU (f), scenario (s), crop (c), and oscillation (o), respectively, and $I_{o,t}$ is the oscillation index. The existence of a linear relationship was assessed by calculating Pearson's correlation from a random bootstrap sample (N = 1,000, with replacement) of crop yield–oscillation index variable pairs. The linear relationship was defined to be significant ($p < 0.1$), if 95 % (two-sided test) of the sampled correlations were either larger or smaller than zero. Thus, a 10 % probability was accepted of wrongly classifying a linear relationship as significant. Note that the relatively high risk level in statistical regression ($p < 0.1$) is commonly used in global climate–yield analysis because of the limited access to high quality yield data at the global scale (e.g., Ray et al., 2015). To check robustness of results, the same analysis was also conducted with the Princeton climate input, different model configurations as well as individual models. Further, to illustrate the effect of using phase-locked indices rather than investigating intra-annual temporal variation (see Section 2.2), the sensitivity of crop yield to these oscillations was also assessed by using the average harvest season oscillation indices as explanatory variable (see Supplement).

2.5 Average crop yield anomalies during strong oscillation phases

The crop-specific average yield anomalies observed during strong oscillation phases were investigated for the actual cropping scenario. The crop yield changes that occur during years when the oscillations are in their strong phases were summarized by the median crop yield anomaly (in percentage) of those years. The median anomaly was calculated using all the GCMs that simulate the crop in question (N=216-297, depending on crop) for the actual scenario with AgMERRA climate input. Strongly negative (positive) phases of the oscillations were defined as the years when the respective oscillation index was smaller (larger) than the 25th (75th) percentile of all yearly index values. The statistical significance ($p < 0.1$) of the changes was assessed by bootstrapping ($n = 1,000$, with replacement) the crop yield anomalies, and calculating the median of each bootstrap sample. If over 95 % (two-tailed test) of the sample of means were either larger or smaller than zero, the change was considered statistically significant.

2.6 Impacts in different cropping systems

To assess how expanding or reducing the extent of irrigated area, and increasing fertilizer use would change the impacts of climate oscillations on crop yields, compared to the actual scenario, the main sensitivity analysis (see description above – Sect. 2.4) was conducted for a set of scenarios (Table 2): i) all cropland was only rainfed (with fullharm setup), ii) all cropland was fully irrigated (fullharm), iii) all cropland was fully fertilized (actual irrigation with fullharm-suffN), and iv) all cropland was fully irrigated and fertilized (fully irrigated with harm-suffN). In addition to analysing how the above mentioned four scenarios compare against the actual scenario, the fully irrigated and rainfed scenarios were also compared. To quantify how the impacts in these cropping systems vary, average sensitivity magnitudes were compared for each crop. Specifically, for a pair of scenarios, the average difference of their absolute sensitivity values was calculated across all oscillations and FPU, where at least one of the scenarios shows a significant sensitivity. To obtain a measure relative to the actual (or irrigated when comparing irrigated and rainfed scenarios) scenario, the average difference values were divided with the average sensitivity magnitude of the actual (or irrigated) scenario for the FPU included. The corresponding equation is:

$$\Delta S_{s12,c} = \sum_{o,f} \frac{|S_{s1,c,f,o}| - |S_{s2,c,f,o}|}{|S_{s1,c,f,o}|} / n_{F,O} * 100 \%, \quad (3)$$

where at least of one $|S_{f,s1,c,o}|$ or $|S_{f,s2,c,o}|$ is statistically significant. $f, s \in \{s1, s2\}$, c , and o are indices of FPU, management scenario, crop, and oscillation respectively. $\Delta S_{s12,c}$ denotes the average proportional sensitivity difference of each crop (c) between the scenarios, while $S_{f,s1,c,o}$ and $S_{f,s2,c,o}$ represent the sensitivity in the respective management scenarios $s1$ and $s2$. $n_{F,O}$ is the number of cases (oscillation and FPU) where at least one of the scenarios has a significant sensitivity.

For each crop, to assess whether the mean sensitivity magnitude difference is statistically significantly different from zero, a distribution of the mean sensitivity magnitude difference was created by calculating the average from bootstrapped (N = 1,000, with replacement) difference values of each FPU and oscillation. For the comparisons with varying fertilizer use, only those

nine GCMs which have data for both ‘fullharm’ and ‘harm-suffN’ settings and thus simulate nutrient stress (Table 1), were included.

3 Results and Interpretation

3.1 Global extent of climate oscillation impacts

5 Globally, climate oscillations have widespread effects on crop yields (Table 2), but both the direction and magnitude of impacts vary spatially and across crops (Fig. 1). ENSO shows the widest impacts on yields of rice (statistically significant sensitivity in 55 % of harvested areas), and soybean (66 %), while IOD and ENSO both show a similar extent of impacts on the yields of wheat and maize (45-50 %). NAO seems to have the smallest impacts on the yields of the crop types inspected here in terms of harvested areas, although it still shows relatively strong influence on wheat (37 %) and maize (27 %) yields. In terms of
 10 sensitivity direction, it is notably more widespread for yield to decrease towards the positive phase of ENSO (i.e. El Niño) for maize, rice and soybean (i.e. negative sensitivity). For IOD and NAO, the results are more mixed, though both show larger harvested areas where yield increases towards the positive phase for wheat. These results are backed up by crop yield anomalies during strong oscillation phases, as they also show widespread average crop yield anomalies during strong oscillation phases (Table S1).

15 **Table 2. Extent of significant sensitivity. Crop-specific harvested area (10^6 ha) extent (and percent of total crop-specific harvested area), where actual crop yield shows statistically significant positive (+) or negative (-) sensitivity to ENSO, IOD and NAO, i.e. there is a statistically significant (two-sided p-value < 0.1) linear relationship between crop yield anomalies and the studied oscillations (see Methods). Extent affected by significant anomalies is shown in Table S1.**

Sensitivity	ENSO		IOD		NAO	
	-	+	-	+	-	+
Maize	48 (32 %)	25 (17 %)	32 (21 %)	44 (29 %)	30 (20 %)	11 (7 %)
Rice	68 (41 %)	23 (14 %)	64 (38 %)	19 (11 %)	6 (4 %)	18 (11 %)
Soybean	39 (52 %)	10 (14 %)	23 (31 %)	21 (28 %)	9 (12 %)	6 (8 %)
Wheat	45 (21 %)	54 (25 %)	33 (16 %)	76 (35 %)	24 (11 %)	55 (26 %)

20 3.2 Impacts in different areas

ENSO’s relationship with crop yield seems to provide the most distinct spatial patterns across the crop types, crop models and oscillations studied here (Figs 1-3, Figs S1-S6, Supplementary zip-file). Crop yields tend to decrease towards positive phase of ENSO (El Niño) in a large proportion of southern Africa, as well as eastern parts of South America and Australia, while

yields seem to increase towards the positive phase on the coast of Peru and eastern Africa (Fig. 1). In general, these results align well with the spatial patterns found in existing studies on the Palmer Drought Severity Index (Dai et al. 1998) and crop productivity (Heino et al. 2018). Also, in terms of model agreement, consistent increase (decrease) of wheat yields in eastern South Asia and parts of the Middle East can be observed for ENSO towards its positive (negative) phase (Figs 1-3). For parts
5 of North America, wheat and soybean seem to be related with opposite impacts. This is potentially because of harvest timing and the related weather conditions; winter wheat is harvested before the summer, while soybean is harvested the following autumn, which is when an ENSO event of opposite sign might have started to develop (Anderson et al. 2017). If the sensitivity for soybean is calculated for ENSO during autumn, it is closer to what is observed for wheat (Fig. 1, Figs S7-S8).

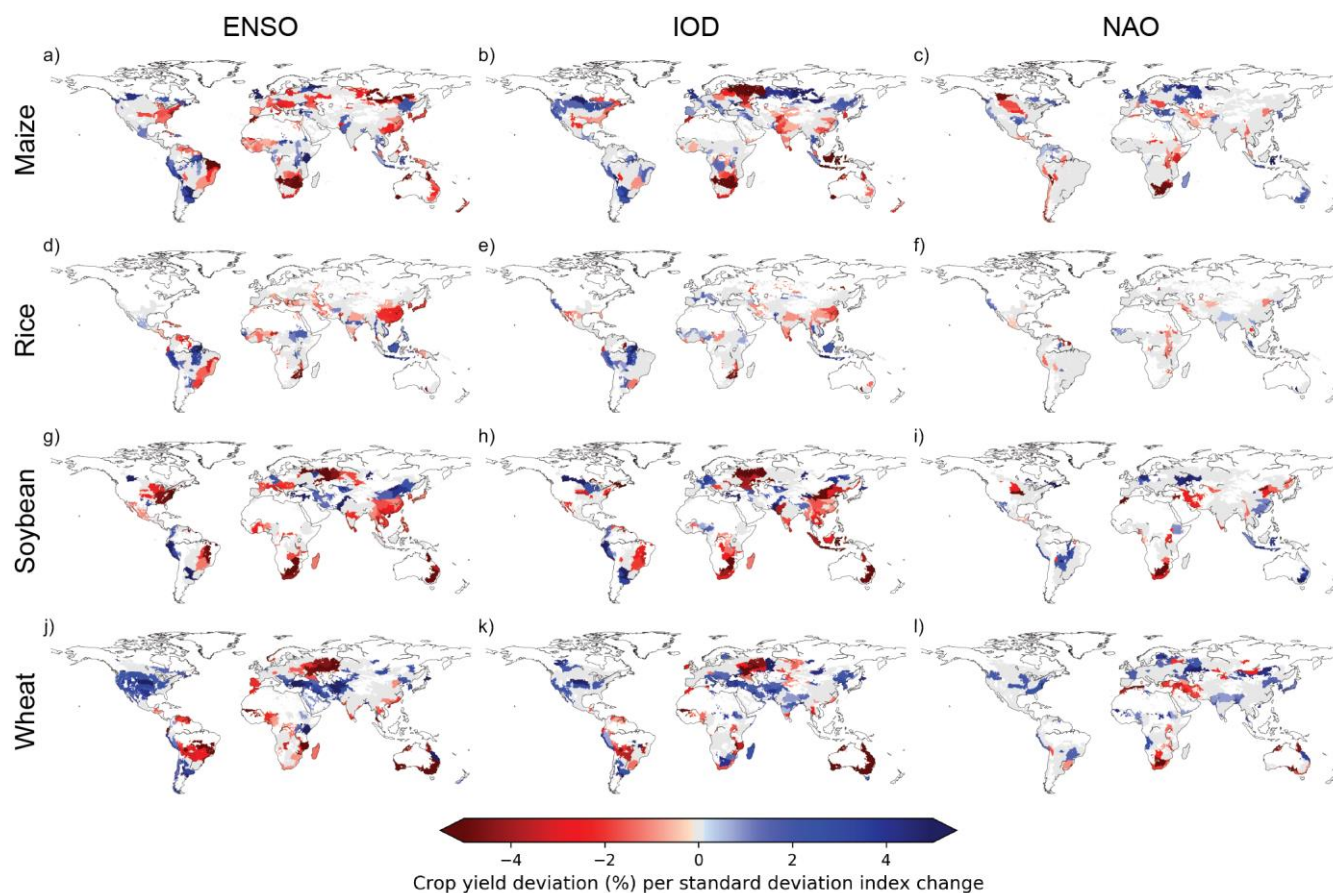

When comparing our results to a study about ENSO's crop yield impacts, which utilized satellite-based crop yields (Iizumi et al. 2014, Iizumi et al. 2018a), the agreement of the impacts varies. Our results agree with existing studies for example for large
10 parts of Africa and eastern Asia, where El Niño is mostly related to negative impacts, while results do not agree as well in North America (wheat) and central South America (maize, soybean). However, it should be noted, that these differences are no surprise, since it has been shown that only a third of global crop yield variability can be attributed to seasonal climate variation (Ray et al. 2015). In contrast to the satellite data, the models used here deliberately focus on weather impacts on crop
15 yield, and do not consider the impacts of e.g. multiple cropping or weather triggered pest outbreaks and management responses, which can also be major contributors to crop yield variations.

For IOD, strong and consistent impacts (Figs 1-2) among crop models (Fig. 3) can be observed in eastern Australia, especially for soybean and wheat (Figs 1-3). This corroborates a previous study conducted on the relationship between IOD and wheat yields, which showed that around 40 % of Australia's wheat yield variability can be attributed to the IOD (Yuan and Yamagata
20 2015). Further, consistent results among models and methods (Figs 1-3) for IOD can be observed in parts of Russia and Central Asia, where the positive (negative) phase of the IOD is related to a decrease (increase) in maize and soybean yields. In India, Southeast Asia, and southern Africa, the impacts of the IOD vary between crops. For example, in southern Africa, wheat shows a positive sensitivity (increasing yield towards the positive phase) while maize and rice show a negative one, again, potentially because of different times of harvest and the related weather conditions. In eastern China, maize, rice and soybean yield
25 variability seems to be related to the IOD to some extent. However, these relationships are less certain, as they are not consistently found by the majority of the individual models (Figure 3).

For NAO, the relationships are generally less certain in terms of model agreement compared to ENSO and IOD (Fig. 3). NAO's most significant impacts can be observed in eastern Europe and the Middle East on maize, soybean and wheat yields (Figs 1-2). In the Middle East, the sensitivity of crop yield to NAO tends to be negative (increasing yield towards the negative phase),
30 while mostly positive sensitivity is found in Europe and western Russia. These results align with results from previous studies about weather patterns and crop productivity (Cullen et al. 2002, Heino et al. 2018, Hurrell et al. 2003). Although, the results

for NAO are relatively similar between different model configurations (Figs S2-S3), the results are not as consistent among the GGCMs as for the other oscillations (Fig. 3).

5 **Figure 1.** Actual maize (a-c), rice (d-f), soybean (g-i), and wheat (j-l) yield sensitivity to ENSO, IOD and NAO at FPU scale. The
sensitivity values are derived using crop yield data from all GGCMs that simulate the crop in question with the AgMERRA climate
input. Statistically insignificant ($p > 0.1$) sensitivity values are marked as zero (colour grey). White colour denotes that the crop in
question is not produced in that area. Results with Princeton climate input and default model setup are shown in Figs S1 and S2,
respectively. Median, maximum and minimum sensitivities as well as consistency across individual models are shown in Figs S3-S6,
10 respectively. Results for individual models are shown in a Supplementary zip-file. Results with oscillation indices calculated in the
harvest season are shown in Fig. S7, with the associated seasons shown in Fig. S8.

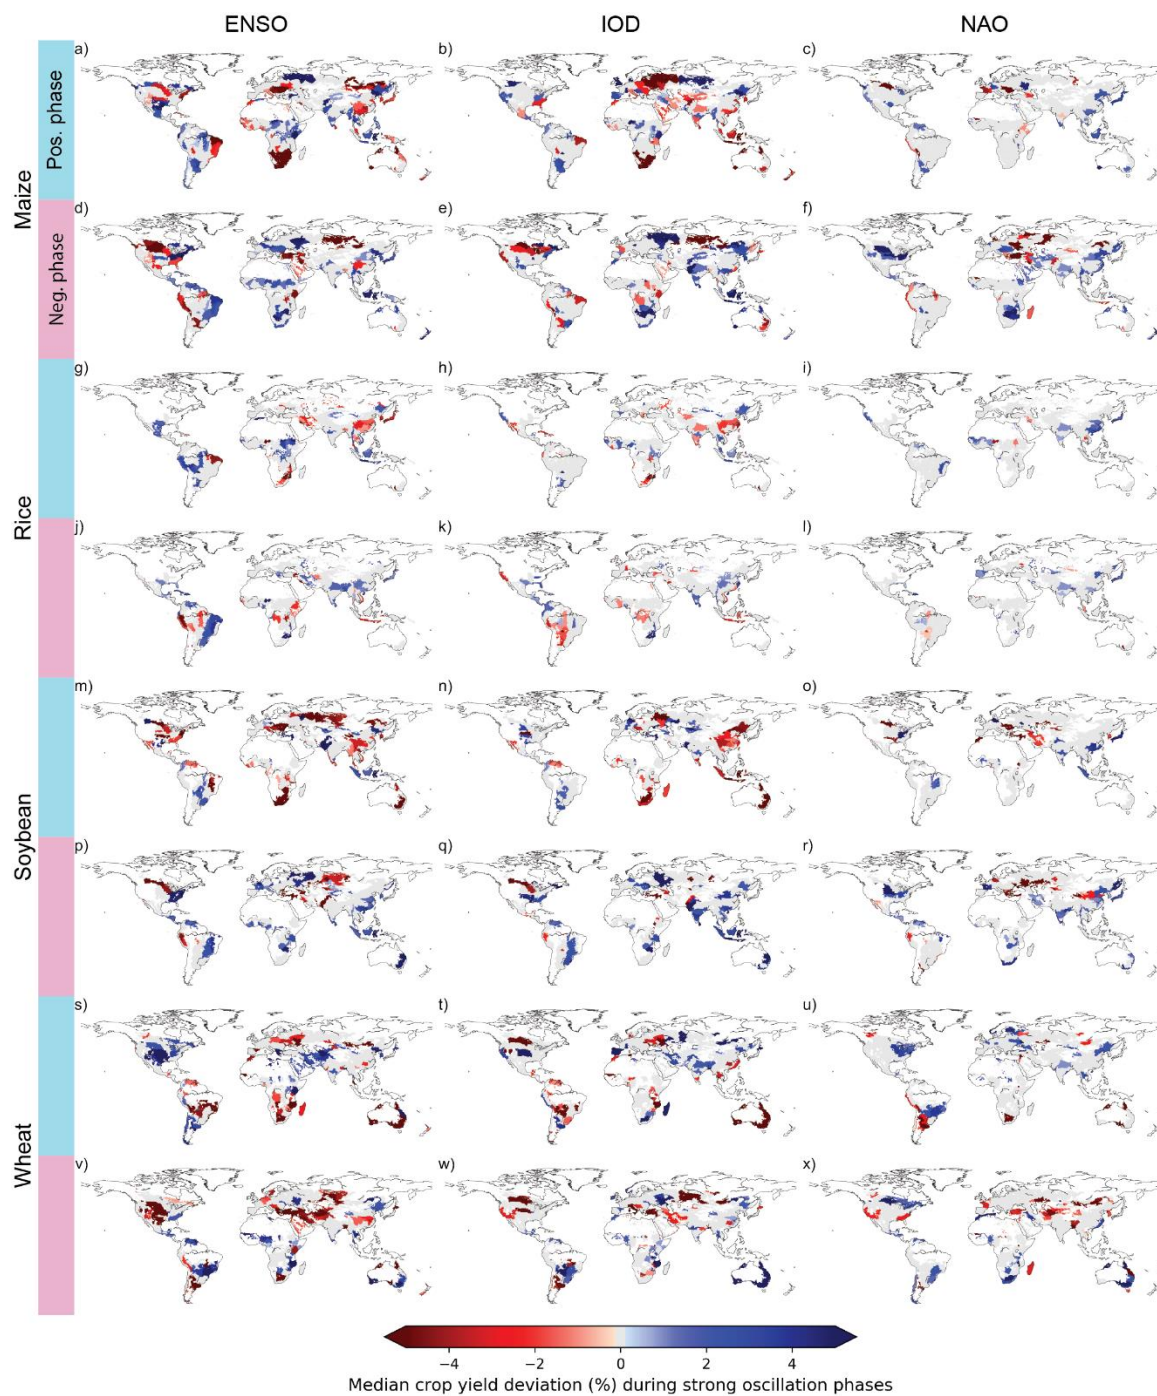

Figure 2. Actual maize (a-f), rice (g-l), soybean (m-r), and wheat (s-x) yield anomalies during strong phases of ENSO, IOD and NAO at FPU scale. The anomaly values are derived from a sample including crop yield data from all GGCMs that simulate the crop in question with the AgMERRA climate input. Statistically insignificant ($p > 0.1$) anomaly values are marked as zero (colour grey).
 5 White colour denotes that the crop in question is not produced in that area.

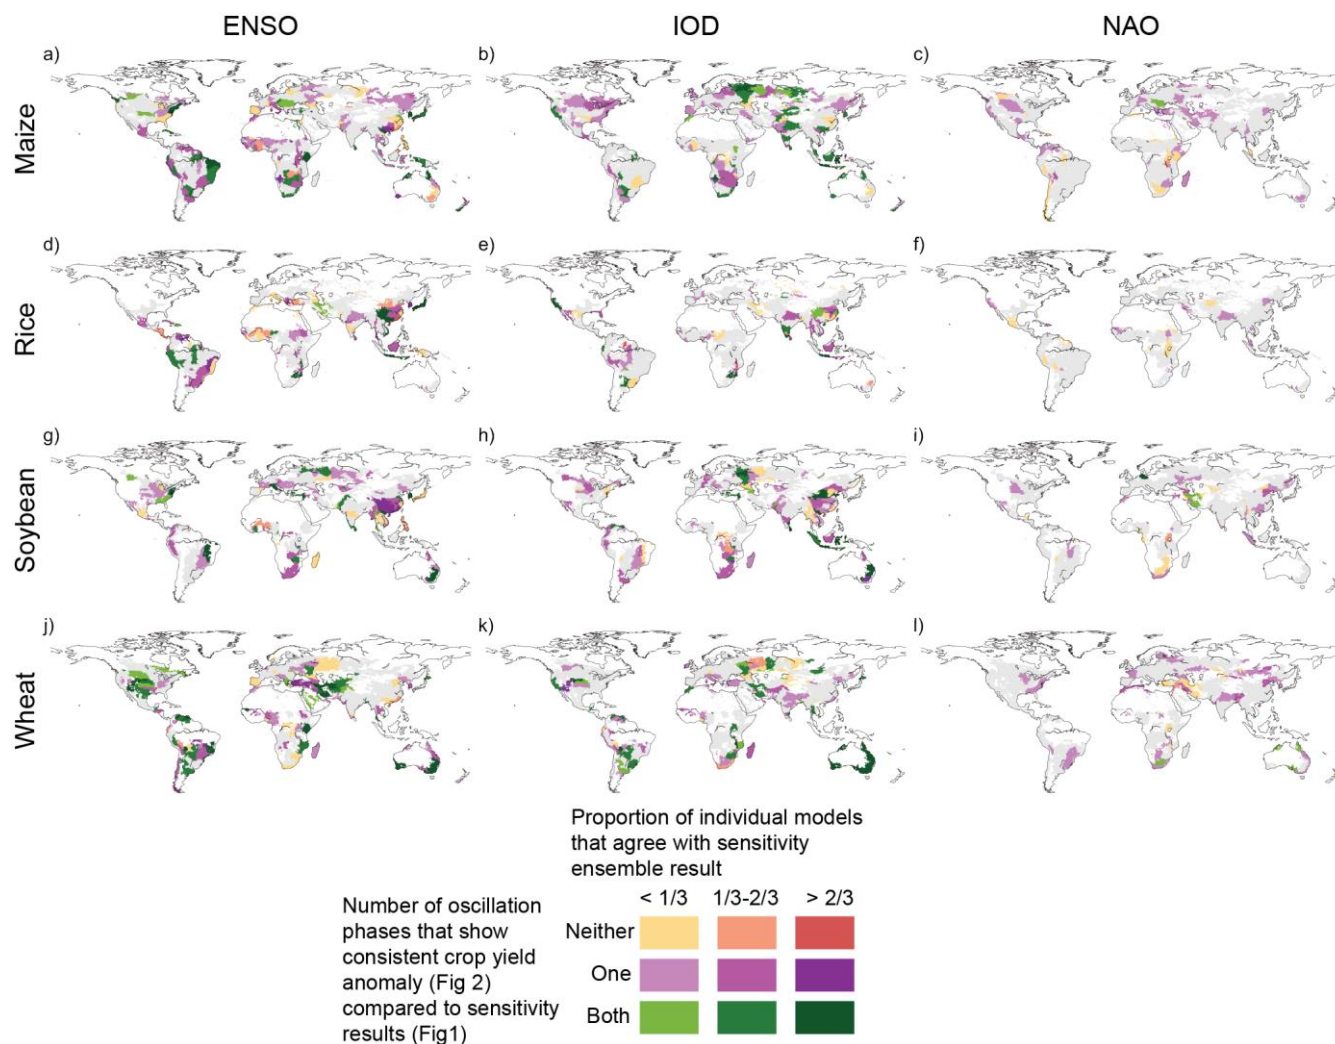

Figure 3. Agreement between models and methods for maize (a-c), rice (d-f), soybean (g-i), and wheat (j-l). The y-axis of the colour bar shows whether there is agreement between the sensitivity analysis (Fig. 1) and the average anomalies during strong oscillation phases (Fig. 2): ‘Neither’ denotes that the strong oscillation phases are not related to significant average crop yield anomalies that are consistent with the sensitivity analysis, ‘One’ means that either positive or negative oscillation phase shows a significant average anomaly that is consistent with the sensitivity result (e.g. positive sensitivity, and positive anomaly during a positive oscillation phase), ‘Both’ means that both phases of the oscillations show consistent average anomalies during the strong oscillation phases (e.g. positive anomaly during a positive oscillation phase, and negative anomaly during a negative oscillation phase in an FPU with positive sensitivity). The x-axis of the colour bar shows the proportion of individual models that show significant sensitivity of same sign compared to the result from the ensemble analysis (see Fig. 1 above, Fig. S6 and Supplementary zip-files). Areas where the ensemble results do not show a statistically significant relationship are marked in grey, while white colour denotes that the crop in question is not grown in that area

3.3 Magnitude of impacts in different cropping systems

- Irrigation plays a key role in reducing crop yield sensitivity to climate oscillations, with yield varying up to three times more (for wheat) across the range of oscillations when comparing fully irrigated and rainfed scenarios (Fig. 4). Comparing rainfed to actual conditions shows that irrigation has already substantially reduced the effects of climate oscillations on crop yields.
- 5 The average difference in sensitivity is largest for rice, where average sensitivity would be over two times higher, i.e. yield would vary two times more across the range of the oscillations. The difference in sensitivity is smallest for soybean (30 %), while maize and wheat show a relative sensitivity increase of 68 % and 63 %, respectively. This ranking is expected, as the majority of rice production areas is irrigated (62 %) and soybean has the smallest irrigated area share of these four crops (8 % globally, Portmann et al. 2010).
- 10 Conversely, average sensitivity would be smaller if crops were fully irrigated without any limitations on water availability, compared to the actual situation, for all the inspected crop types. Benefits of further irrigation are limited by its current use, which might be why rice shows the smallest difference in average impacts (most of the rice harvested area is already irrigated). The average decrease in crop yield sensitivity to the oscillations is largest for soybean (43 %, i.e. yield varying 43 % less across the oscillations compared to actual conditions, Fig. 4) and wheat (48 %), while maize shows a 34 % average decrease.
- 15 Unlimited fertilizer (fully fertilized scenario) use yields statistically significantly larger average sensitivity compared to actual conditions for maize (22 %) and wheat (18%) (Fig. 3). For these crops, these climate oscillations have a stronger impact on yields in cropping systems that do not have limitations related to nutrient availability. This reflects previous research that has found increased crop yield variability under additional fertilizer inputs (Müller et al. 2018). This is potentially because in low crop yield years, fertilizer use is not the main limiting factor, so yields are not significantly improved, while in years when
- 20 climate conditions are suitable for crop growth, yields become even higher, which would increase the sensitivity value as well (Fig. S19). Soybean has very little change in sensitivity under full fertilisation. This is likely because it is a legume and has lower nitrogen requirements – nitrogen availability is not even considered in some models.
- Combining both unlimited irrigation and fertilizers, all of the crop types show smaller average sensitivity compared to the actual cropping system scenario (Fig. 4). The decreased sensitivity due to increased irrigation dominates the increased
- 25 sensitivity due to increased fertilizer use. However, the differences in sensitivity magnitude are large between crops, with soybean having the largest decreases in average sensitivity magnitude (41 %), and rice having the smallest (12 %).
- The above mentioned results can be observed spatially Supplementary Figs S9-S17), which e.g. clearly show that, in most areas, the sensitivity magnitude is larger in the rainfed as well as fully fertilized scenarios, i.e. yields vary more across the range of the oscillation index. The spatial results also highlight areas with potential to reduce impact of oscillations, for example
- 30 for ENSO in northern South America (soybean and rice) as well as for IOD in Australia (wheat), where high sensitivity to the respective oscillations can be observed for the actual scenario.

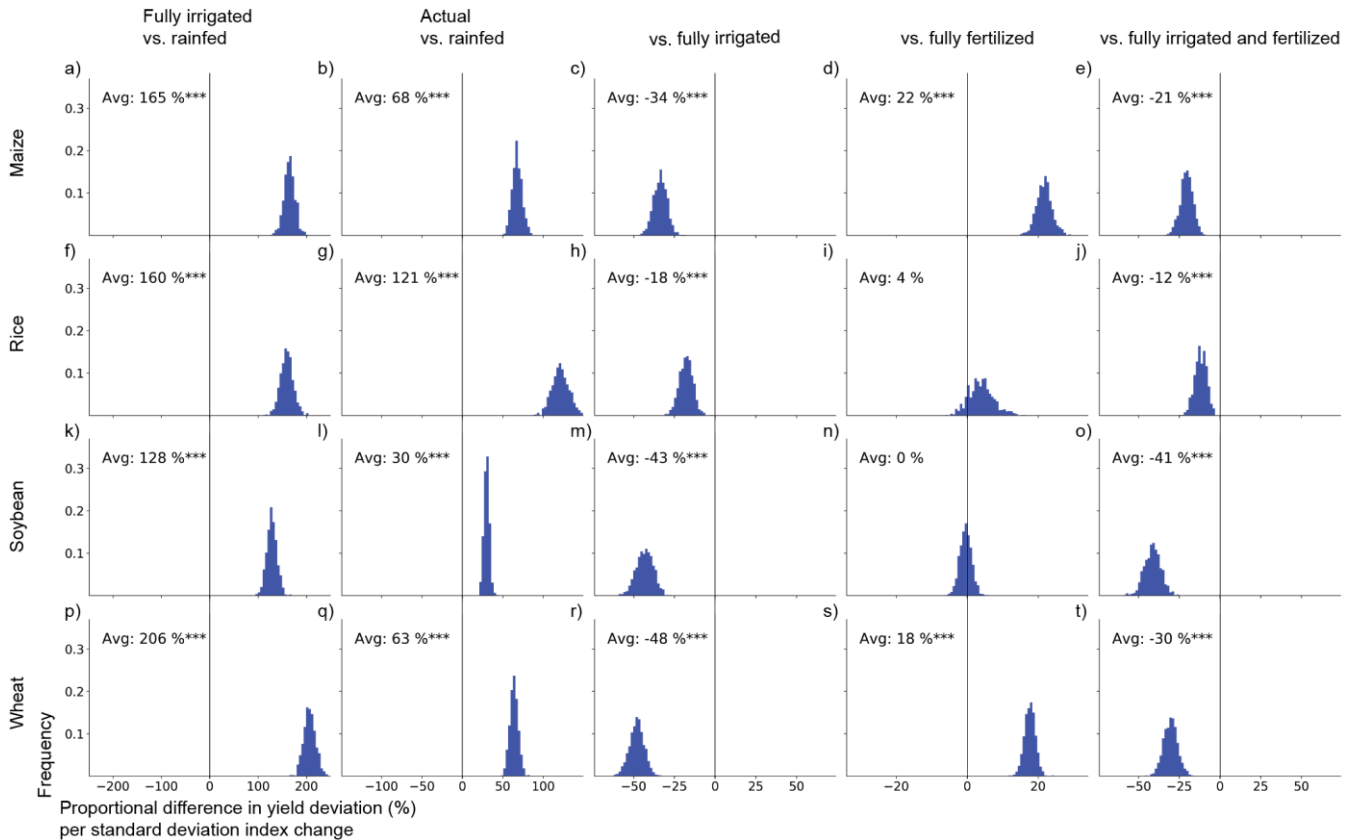

Figure 4. Relative average difference in sensitivity magnitude of maize (a-e), rice (f-j), soybean (k-o) and wheat (p-t) between a range of cropping scenarios through all the studied oscillations and FPU. To quantify how the impacts in these cropping systems vary, average sensitivity magnitudes were compared for each crop. Specifically, for a pair of scenarios, the average difference of their absolute sensitivity values were calculated across all oscillations and FPU, where at least either scenario shows a significant sensitivity. To obtain a measure relative to the actual (or irrigated when comparing irrigated and rainfed scenarios) scenario, the average difference values were divided with the average sensitivity magnitude of the actual (irrigated) scenario for the FPU included. For each crop, to assess whether the mean sensitivity magnitude difference is statistically significantly different from zero, a distribution of the mean difference was created by calculating the average from bootstrapped (N = 1,000, with replacement) difference values of each FPU and oscillation. For the scenarios with varying fertilizer use set-up, we included only those nine GCMs which have data for both ‘fullharm’ and ‘harm-suffN’ settings and also simulate nutrient stress, i.e. pDSSAT, EPIC-Boku, EPIC-IIASA, GEPIC, pAPSIM, PEGASUS, EPIC-TAMU, ORCHIDEE-crop, and PEPIC. Triple, double and single asterisks denote the confidence level at 99.9 %, 99 % and 90 %, respectively. Maps of sensitivity for each cropping system are shown in Figs S9-S13 and difference in sensitivity magnitude in Figs S14-S18. Please note different scale in x-axis between the columns.

15 4 Discussion

In this study, we inspected the historical relationship between crop yield variability and climate oscillations in a range of cropping systems by utilizing an ensemble of historical crop yield simulations generated in GGCMI. The results of this study highlight the widespread impacts that ENSO, IOD and NAO have on crop yields at the global scale, as well as potential options for mitigation. Further, we find robust impacts for these oscillations in many areas around the globe, e.g. in southern parts of

Africa and northern South America for ENSO, and in eastern Australia for IOD, where these information can potentially be utilized in efforts mitigating weather driven variations in crop productivity (Iizumi et al. 2018b)

Our results join existing research (Müller et al. 2018, Schauburger et al. 2016, Okada et al., 2018) in highlighting the major role of irrigation in mitigating climate related crop yield variations, and thus securing global food production. This is an important point, since water supplies are highly stressed in many important crop production areas (Kummu et al. 2016), which are also impacted by climate oscillations, such as parts of North America and South Asia. Thus, diminishing water resources could pose a major barrier in mitigating future negative impacts related to climate oscillations and climate variability in general. This can be very problematic, given that climate change will likely increase the occurrence of extreme weather in the future (Coumou and Robinson 2013). However, it should also be noted that there is substantial potential to improve water use efficiency with integrated crop water management measurements (Jägermeyr et al. 2016).

Interestingly, at a global level, increasing fertilizer use does not seem to decrease the sensitivity of crop yields to oscillations, potentially because low crop yield years remain the same while in years when conditions are suitable for crop growth, yields become even higher (Müller et al. 2018), which would increase the sensitivity value as well. This explanation aligns with previous research, which has shown that increasing fertilizer use has limited potential to increase crop yields during years when weather is not suitable for crop growth (Liebig's law). In other words, additional fertilizer use in years with unfavourable seasonal climate condition does not lead to yield gain and is not cost effective. Therefore, decision support systems which guide farmers about optimal fertilizer use under predicted growing season climate can be useful to avoid investments in fertilizers in bad years (Hayashi et al., 2018).

4.1 Limitations and way forward

The selection of the time windows for calculating the oscillation metric can have an impact on the spatial crop yield sensitivity signature, as briefly illustrated in this study as well (Fig. 1, Fig. S7). Previously used approaches for identifying these relationships include e.g. looking at crop yield anomalies during the year (Heino et al. 2018, Iizumi et al. 2014, Yuan and Yamagata 2015) and years around (Anderson et al. 2017) strong oscillation anomalies. In these studies strong oscillation anomalies are calculated either for the season that the oscillations shows the strongest signal (Heino et al. 2018, Anderson et al. 2017, Yuan and Yamagata 2015) or the harvest season (Iizumi et al. 2014). In general, it can be said that it is very difficult to find metrics for the oscillations that would work perfectly everywhere. The justification for the methods used here is to look at how crop yields vary during the year after these oscillations show their strongest signal, which can provide valuable information for early warning systems.

Future work could try to trace intermediate effects, e.g. combining the effect of oscillations on weather, the effect of each aspect of weather on crop planting, development and harvest, and the final result in terms of crop yield. Such research could

additionally provide useful information for decreasing crop yield variability, and thus increasing the resilience of crop production to climate related variation.

The data used here are from state of the art global gridded crop models included in the GGCM of AgMIP. However, major uncertainties in the simulated crop yields still exist, and the relationships observed here between crop yields and these oscillations are often not consistent throughout the ensemble of crop models (see Fig. 3). Differences and uncertainties among the models arise e.g. from soil and crop type parametrisations as well as handling of water and nutrient stress (e.g. Folberth et al. 2016). Additionally, uncertainties in these GGCMs arise from the simulated cropping systems, as simulations have only a single annual harvest per crop and per grid cell, whereas multiple harvests are common for e.g. rice. In general, simulated crop yields seem to be most reliable in high nutrient-input areas (Müller et al. 2017), where observed climate variability also explain a majority of reported crop yield variation (Ray et al. 2015).

This study has included comparison with fully fertilized and irrigated management scenarios intended to capture (unattainable) ideal management, with no water or nutrient stress anywhere. This helps understand the physical potential of the management measures for mitigating crop yield variability related to these oscillations, according to the models used. In future, practical limitations could also be taken into account by limiting water and fertilizer use to locally available resources.

The three climate oscillations included here are only a share of the whole range of periodically fluctuating climatological phenomena that could impact crop growing conditions. Thus, studying the relationship between simulated crop yields and other climate oscillations, not included here, such as Scandinavian Pattern or the Arctic Oscillation, would provide additional insights to this topic, as demonstrated by a recent study by Ceglar et al. (2017).

5 Conclusions

This study strengthens the evidence that climate oscillations are drivers of crop yield variability around the world. In several areas, where these oscillations show robust impacts on crop production, e.g. Australia, southern Africa, as well as parts of North and South America, local disaster control as well as global efforts can already benefit from utilizing these known relationships in mitigating crop production against climatologically driven variations. Information for maintaining the stability of global crop production is of high importance, given that anticipated climate change and population growth will keep increasing the pressure towards the global food system. Finally, we want to highlight the importance of water in mitigating crop yield variability. Our results suggest that increases (decreases) in the extent of irrigated area would, on average, reduce (amplify) the impacts of these oscillations on crop yields. Hence, sustainable water use is crucial for maintaining the long-term stability of the global crop production system.

6 Code and data availability

The processing scripts are available from github: https://github.com/matheino/crops_and_oscillations. The simulated crop yield data were retrieved from the GGCM data archive: <http://www.rdcep.org/research-projects/ggcm>.
