**Abstract.** The Mediterranean (MED) basin is a climate change hot-spot that has seen drying and a pronounced increase in heatwaves over the last century. At the same time, it is experiencing increasing heavy precipitation during wintertime cold spells. Understanding and quantifying the risks from compound events over the MED is paramount for present and future disaster risk reduction measures. Here, we apply a novel method to study compound events based on dynamical systems theory and analyse compound temperature and precipitation anomalies over the MED from 1979 to 2018. The dynamical systems analysis measures the strength of the coupling between different atmospheric variables over the MED. Further, we consider compound hot-dry days in summer and cold-wet days in winter. Our results show that these hot-dry and cold-wet compound days are associated with maxima in the temperature-precipitation coupling parameter of the dynamical systems analysis. This indicates that there is a strong interaction between temperature and precipitation during compound events. In summer, we find a significant upward trend in the coupling between temperature and precipitation over 1979-2018, which is likely driven by a stronger coupling during hot and dry days. Thermodynamic processes associated with long-term MED warming can best explain the trend. No such trend is found for wintertime cold-wet compound events. Our findings suggest that long-term warming strengthens the coupling of temperature and precipitation which intensifies hot-dry compound events.

## 1 Introduction

The Mediterranean (MED) basin is considered a climate change hot-spot and has seen winter drying as well as a pronounced increase in summer heatwaves over recent decades (e.g., Mariotti, 2010; Hoerling et al., 2012; Shohami et al., 2011; Nykjaer, 2009). Summer heatwave trends observed over the historical period are mainly driven by thermodynamic changes, such as increasing temperatures, that exacerbate soil drying and daily maximum temperatures. Drying trends during winter are associated with dynamical changes, likely triggered by increased greenhouse gas and aerosol forcing (Hoerling et al., 2012). However, wintertime heavy precipitation, often in the form of snowfall, has not decreased as rapidly as one may expect (Faranda, 2019).

Many studies have investigated climate change projections over the MED under high greenhouse gases emission scenarios, providing strong evidence for a continuation of the trends witnessed in the historical period, and much warmer and drier conditions by the end of the 21<sup>st</sup> century (Zappa et al., 2015; Mariotti et al., 2015; Scoccimarro et al., 2016; Hochman et al., 2018; Samuels et al., 2018; Seager et al., 2014; Barcikowska et al., 2020; Goubanova and Li, 2007; Giorgi and Lionello, 2008; 25 Giannakopoulos et al., 2009; Beniston et al., 2007). Such climatic changes imply more severe and frequent summer heatwaves and droughts (Fischer and Schär, 2010; Giorgi and Lionello, 2008; Beniston et al., 2007; Giannakopoulos et al., 2009), but also an increase in precipitation extremes notwithstanding the decline in total precipitation (Scoccimarro et al., 2016; Samuels et al., 2018; Goubanova and Li, 2007; Giannakopoulos et al., 2009). Similar changes are expected during winter, including a reduction of cold spell intensity. For example, Hochman et al. (2020) showed that Cyprus Lows – synoptic low-pressure 30 systems that develop over the Eastern MED and can drive cold spells and heavy precipitation over the Levant – are projected to decrease in frequency and rain-bearing capacity in the future. Changes in atmospheric dynamics, such as an amplified "monsoon-desert mechanism" in summer (Rodwell and Hoskins, 1996; Cherchi et al., 2016; Kim et al., 2019; Wang et al., 2012) or a poleward shift of the tropical belt in winter (Hu and Fu, 2007; Seidel et al., 2008; Peleg et al., 2015; Totz et al., 2018), may play a significant role in enhancing the drying of the MED in future climates.

35 In recent years, it has become increasingly clear that weather-related impacts often result from the compounding nature of several variables, even if the variables are not extreme when analysed independently. For hazards it is thus important to consider compound, or multi-variate, events (Zscheischler et al., 2018; Leonard et al., 2014), as well as cascading events (de Ruiter et al., 2020). Such compound events can lead to socio-economic damages exceeding those expected if the individual hazards were to occur separately (e.g., de Ruiter et al., 2020; Barriopedro et al., 2011). The MED region is highly vulnerable to compound hot- 40 dry events, such as the co-occurrence of heatwaves and droughts (Zampieri et al., 2017; Li et al., 2009). Wintertime cold-wet events, especially when associated with snowfall, may also result in costly regional impacts (e.g. Hochman et al., 2019; Bisci et al., 2012).

Here, we specifically seek to characterise precipitation - temperature compound events over the MED in terms of the coupling between the large-scale precipitation and temperature fields. This allows us to relate long-term changes in compound events 45 to their underlying physical drivers. We focus on compound hot-dry and cold-wet events during summer (June-July-August, JJA) and winter (December-January-February, DJF), respectively. To diagnose the coupling between atmospheric variables, we apply a method based on dynamical systems theory that reflects the dynamical evolution of the atmosphere (Faranda et al., 2020; De Luca et al., 2020) and is well-suited to diagnosing changes in atmospheric properties (Faranda et al., 2019). The article is structured as follows: Section 2 describes the methods, data and statistical tests. Sections 3-4 present the results. 50 Specifically, Section 3 focuses on the strength of the dynamical coupling during JJA. Section 4 investigates the large-scale patterns of sea-level pressure (SLP), temperature and precipitation observed during the days when the dynamical coupling is high in both JJA and DJF, and relates these to the compound hot-dry and cold-wet events. Finally, Section 5 summarises and discusses our main findings, and outlines future research opportunities.

## 2 Methods and data

### 55 2.1 Dynamical systems metrics

In this study, we use a dynamical systems approach to compute two metrics:  $\theta^{-1}$  and  $\alpha$ .  $\theta^{-1}$ , which we term *persistence*, is very intuitively a measure of the average residence time of the system around a state of interest. Hence, the higher the value of  $\theta^{-1}$ , the more likely it is that the preceding and future states of the system will resemble the current state over relatively long timescales (Faranda et al., 2017b; Messori et al., 2017; Hochman et al., 2019).  $\alpha$ , which we term *co-recurrence ratio*, is a  
60 measure of the dynamical coupling between two variables.

The calculation of the dynamical systems metrics stems from the combination of Poincaré recurrences with extreme value theory (Lucarini et al., 2012; Freitas et al., 2010; Faranda et al., 2020). By *recurrences* we refer to the system being analysed returning arbitrarily close to a previously visited state. Given an atmospheric variable  $x$ , we consider a state of interest  $\zeta_x$ . In our case, this would be an instantaneous configuration of that variable, such as a latitude-longitude temperature map on a given  
65 day over the MED. We then consider recurrences to be those states that are close to  $\zeta_x$ , namely other timesteps at which the selected variable takes a very similar configuration. In order to quantify how close two configurations are to one another, we use the Euclidean distance between latitude-longitude maps. Based on the properties of these recurrences, we can diagnose the dynamical systems persistence  $\theta_x^{-1}$  of the state  $\zeta_x$ .  $\theta_x^{-1}$  measures the average residence time of the system around  $\zeta_x$  and it has the units of the timestep of the dataset being analysed. If we extend the analysis to two variables,  $x$  and  $y$ , we can then  
70 compute a co-persistence  $\theta_{x,y}^{-1}$  based on recurrences around a joint state of interest  $\zeta = \{\zeta_x, \zeta_y\}$ . In our analysis, the joint state  $\zeta = \{\zeta_x, \zeta_y\}$  would simply be the state consisting of the combined instantaneous precipitation and temperature maps.

We further define the co-recurrence ratio  $\alpha$  between  $x$  and  $y$ . Given a state  $\zeta = \{\zeta_x, \zeta_y\}$ , the co-recurrence ratio  $0 \leq \alpha \leq 1$  measures the number of cases where  $x$  resembles  $\zeta_x$  given that  $y$  resembles  $\zeta_y$ , versus the number of cases when only  $x$  resembles the relevant reference state. When  $\alpha = 0$ , there are no co-recurrences of  $\zeta = \{\zeta_x, \zeta_y\}$  when we observe a recurrence  
75 of  $\zeta_x$ . When  $\alpha = 1$ , recurrences of  $\zeta_x$  are always also co-recurrences of  $\zeta = \{\zeta_x, \zeta_y\}$ . Hence,  $\alpha$  may be interpreted as a measure of the dynamical coupling between  $x$  and  $y$ . However,  $\alpha$  does not indicate causality: indeed, the order of  $x$  and  $y$  may be exchanged without affecting the value of  $\alpha$ . For a schematic depiction of the interpretation of  $\alpha$ , and for the mathematical details of the calculations of  $\theta^{-1}$  and  $\alpha$ , we refer the reader to Faranda et al. (2020).

In our analysis, we consider each timestep in our datasets in turn as the state of interest  $\zeta$ . The final result of our analysis is  
80 therefore a value for each indicator and each timestep for the chosen geographical domain. We term the days with  $\alpha > 90^{th}$  quantile of the full-year distribution over the whole time-period being analysed *compound dynamical extremes* (CDEs). The two indicators, both in their monovariate and bivariate forms, successfully reflect large-scale features of atmospheric motions, and have recently been applied to a range of different climate variables over different geographical domains (Faranda et al., 2017a, b, 2019, 2020; Messori et al., 2017; Rodrigues et al., 2018; Hochman et al., 2019, 2020; De Luca et al., 2020).

## 85 2.2 Data

We use the European Centre for Medium-Range Weather Forecasts' (ECMWF) ERA5 reanalysis over 1979-2018, with a spatial horizontal resolution of  $0.25^\circ$  and a 6-hourly temporal resolution (C3S, 2017). Our MED domain follows the "Full Mediterranean" region described in Giorgi and Lionello (2008). For ERA5, this corresponds to  $27.75\text{--}48.00^\circ\text{N}$ ,  $9.75^\circ\text{W}\text{--}39.00^\circ\text{E}$ . To improve the robustness of our results, we have repeated the bulk of the analysis on ERA-Interim (Dee et al., 2011) and ERA5 10-member ensemble (C3S, 2017) (see Supplementary Material). We use the 6-hourly data to compute daily maximum and minimum 2m temperature (K) and daily total precipitation (mm), from now on termed Tmax, Tmin and P respectively. Hot-dry days are JJA days experiencing positive Tmax and negative P anomalies. Similarly, cold-wet days are DJF days experiencing negative Tmin and positive P anomalies. These are collectively referred to as 'compound events'. We also analyse daily-mean sea-level pressure (SLP, hPa).

## 95 2.3 Statistical tests

The statistical significance of the Sen's slopes (Sen, 1968) of the  $\alpha$  and  $\theta^{-1}$  time-series is verified using the Mann-Kendall test (Mann, 1945) from the R package '*modifiedmk\_v1.4.0*'. The Sen's slopes provide information about the steepness of the trends. If the Sen's slope is positive (negative) the corresponding trend is increasing (decreasing).

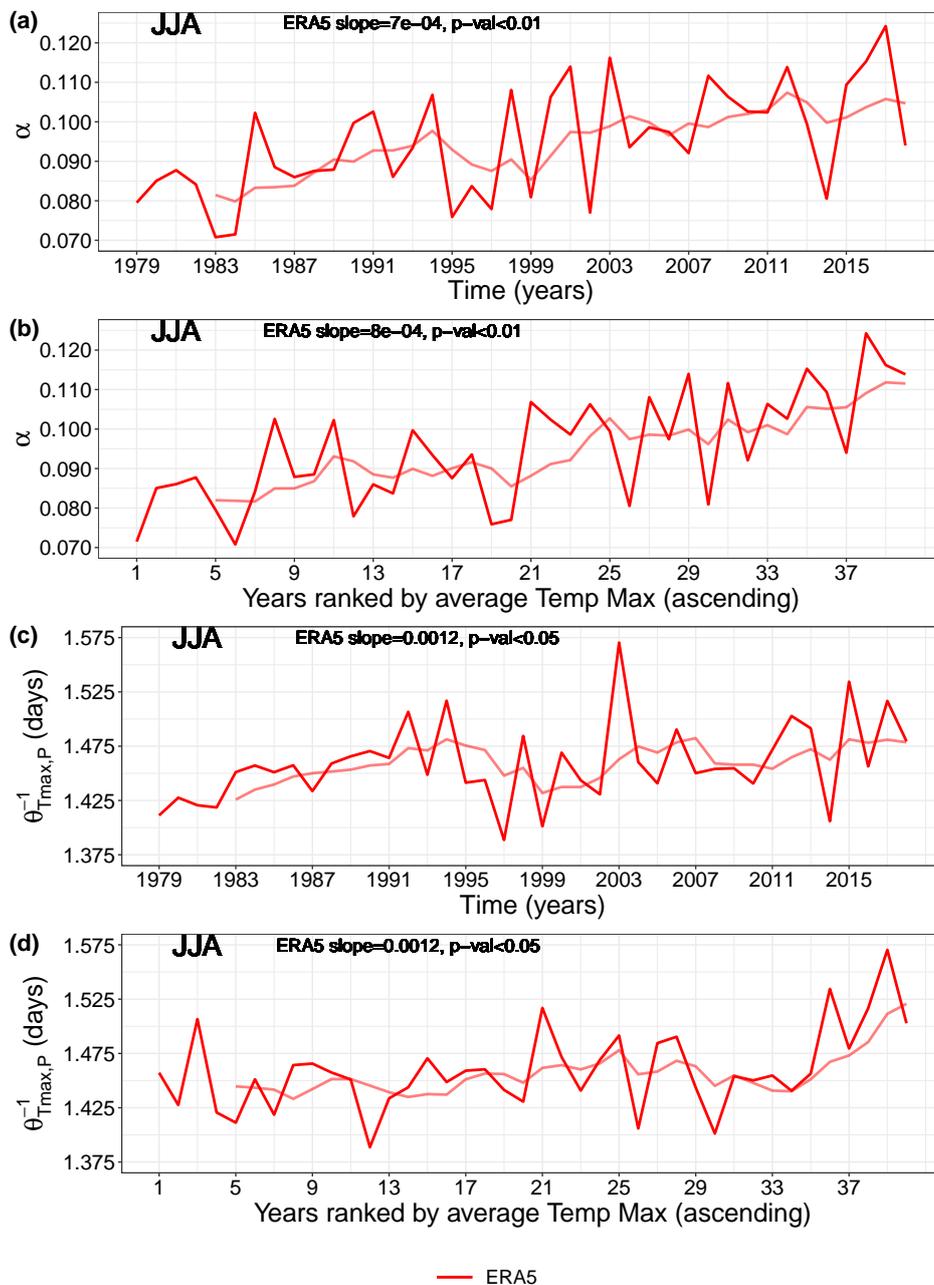

The statistical significance of SLP, Tmax, Tmin and P composite anomalies occurring during CDEs is computed using a one-tailed Mann-Whitney test at the 5% confidence level (Mann and Whitney, 1947). The null hypothesis is that a randomly selected anomaly value during a CDE is equally likely to be less than or greater than a randomly selected value from the days that are not CDEs. The alternative hypothesis is that during JJA (DJF), the SLP and Tmax (Tmin) anomalies observed during CDEs are higher (lower) than the those observed during other days. For P in JJA (DJF), the alternative hypothesis is that anomalies observed during CDEs are lower (higher) than those during other days. To avoid incurring Type I errors (or false positives), we apply the Bonferroni correction to all p-values when considering single-gridpoint data (Bonferroni, 1936). The one-tailed Mann-Whitney test is also applied to the histograms and cumulative distribution functions (CDFs) of the anomaly means occurring during CDEs versus all other days.

## 3 Temperature-precipitation coupling

During JJA, the co-recurrence ratio ( $\alpha$ ) between Tmax and P shows a significant upward trend (p-value  $<0.001$ ) over 1979-2018 (Figures 1a and S1a). This points to an increasingly strong coupling between Tmax and P over time. During DJF, we also observe positive, albeit non-significant  $\alpha$  trends for all three reanalysis products (Figure S2). There is a clear correlation between  $\alpha$  and summer mean Tmax, as highlighted in Figures 1b and S1b. Indeed, ranking  $\alpha$  values by JJA-averages of Tmax results in positive and statistically significant trends (p-values  $<0.001$ ), comparable in magnitude to those seen in Figures 1a and S1a. Moreover, both a regression analysis and the two-sided Spearman's rank correlation test (Corder and Foreman, 2014) between JJA  $\alpha$  values and JJA average Tmax over the MED show a clear association between them (Figure S3). Trends in the

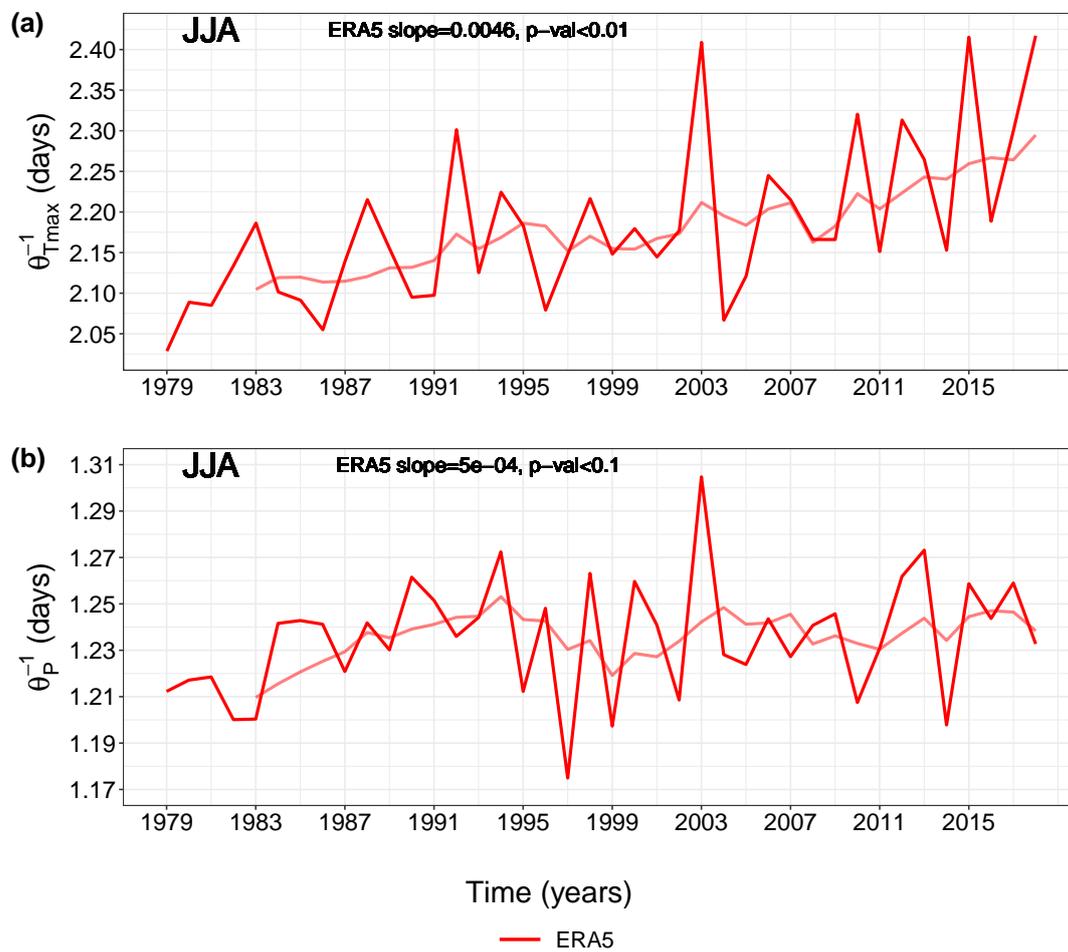

$\alpha$  time-series of both CDE and non-CDE days are upward and statistically significant (Figure S4), pointing to a general shift in the  $\alpha$  distribution towards higher values.

**Figure 1.** Co-recurrence ratio ( $\alpha$ ) and local co-persistence  $\theta_{T_{max},P}^{-1}$  JJA means for ERA5 during the 1979-2018 period over the Mediterranean. (a)  $\alpha$  JJA means; (b)  $\alpha$  ranked according to ascending JJA average Tmax; (c)  $\theta_{T_{max},P}^{-1}$ ; and (d)  $\theta_{T_{max},P}^{-1}$  ranked according to ascending JJA average Tmax. The thin lines are 5-year moving averages. The Sen's slopes and p-values are also shown.  $\alpha$  is computed from Tmax and P.

We next compute the local co-persistence ( $\theta_{Tmax,P}^{-1}$ ) trends during JJA (Figures 1c and S1c) in analogy to Figures 1a and S1a. The significant upward trends (p-value <0.05 for ERA5 and ERA5 ensemble, and p-value <0.01 for ERA-Interim) in  $\theta_{Tmax,P}^{-1}$  imply a trend towards longer joint spatial patterns of Tmax and P over the MED within the observational period. Restricting the analysis to hot-dry days highlights similar trends (not shown), pointing towards increasingly long hot-dry events over the region. As for  $\alpha$ , changes in co-persistence map directly onto changes in average Tmax in JJA (Figures 1d and S1d). Interestingly, there is a clear peak in  $\theta_{Tmax,P}^{-1}$  during summer 2003 for all reanalysis products, coinciding with the extreme 2003 European heatwave (Black et al., 2004; Fischer et al., 2007; Stott et al., 2004). The trends in  $\theta_{Tmax,P}^{-1}$  reflect trends in the (univariate) local persistence of Tmax ( $\theta_{Tmax}^{-1}$ ) and P ( $\theta_P^{-1}$ ) (Figures 2 and S5). Trends in  $\theta_{Tmax}^{-1}$  (Figures 2a and S5a) are stronger than those in  $\theta_P^{-1}$  (Figures 2b and S5b). This strengthens our interpretation of Tmax as playing a predominant role in setting the observed positive trends in the dynamical indicators.

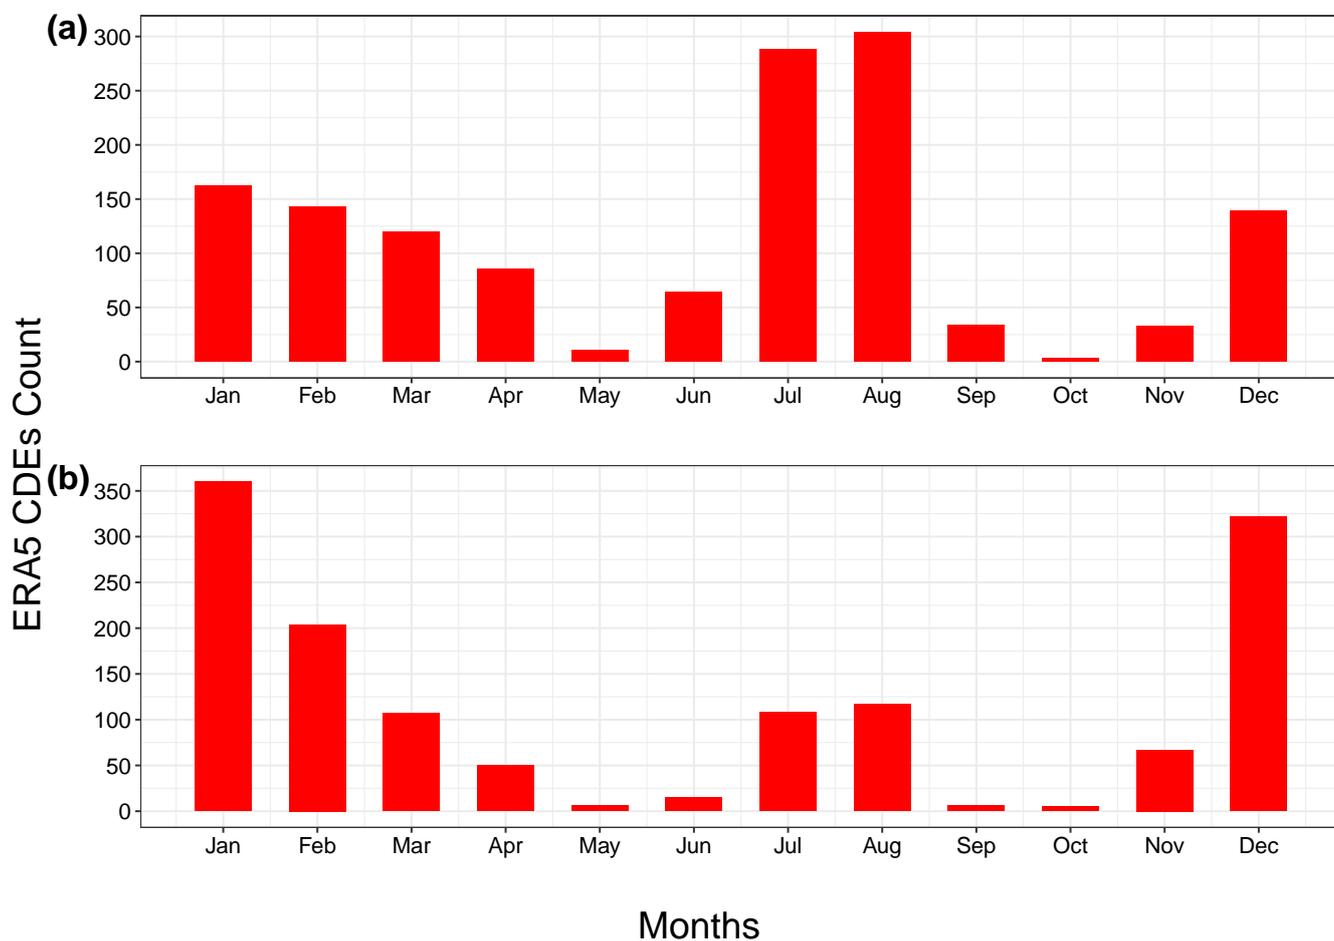

**Figure 2.** As Figure 1c but for univariate local persistence of (a) Tmax ( $\theta_{Tmax}^{-1}$ ) and (b) P ( $\theta_P^{-1}$ ).

## 4 Compound dynamical extremes (CDEs) linked to compound hot-dry and cold-wet events

### 4.1 Seasonality of CDEs

- 130 We next investigate the temporal distribution of CDEs. For  $\alpha$  computed on Tmax and P, all three reanalysis products display CDEs clustering in July and August, with a secondary maximum in DJF (Figures 3 and S6). For  $\alpha$  computed on Tmin and P, most CDEs occur during DJF, with a secondary maximum in July and August (Figures 3b and S6b). This holds for all reanalyses except ERA-Interim, which shows the highest counts during July and August. Such difference may be linked to ERA-Interim's lower horizontal resolution ( $0.75^\circ$ ), leading to a bias in the quantification of P events. For both variable combinations, the
- 135 two shoulder seasons (i.e. spring and autumn) display very few CDEs. In Faranda et al. (2017a), the authors hypothesised that during autumn and spring the atmospheric flow sits on a saddle-like point of the dynamics, while winter and summer represent more stable basins of attraction. Assuming that distinct attractors indeed exist for winter and summer, we thus interpret the low CDE counts as the result of the atmospheric flow exploring both summer and winter configurations, resulting in rarer co-recurrences.

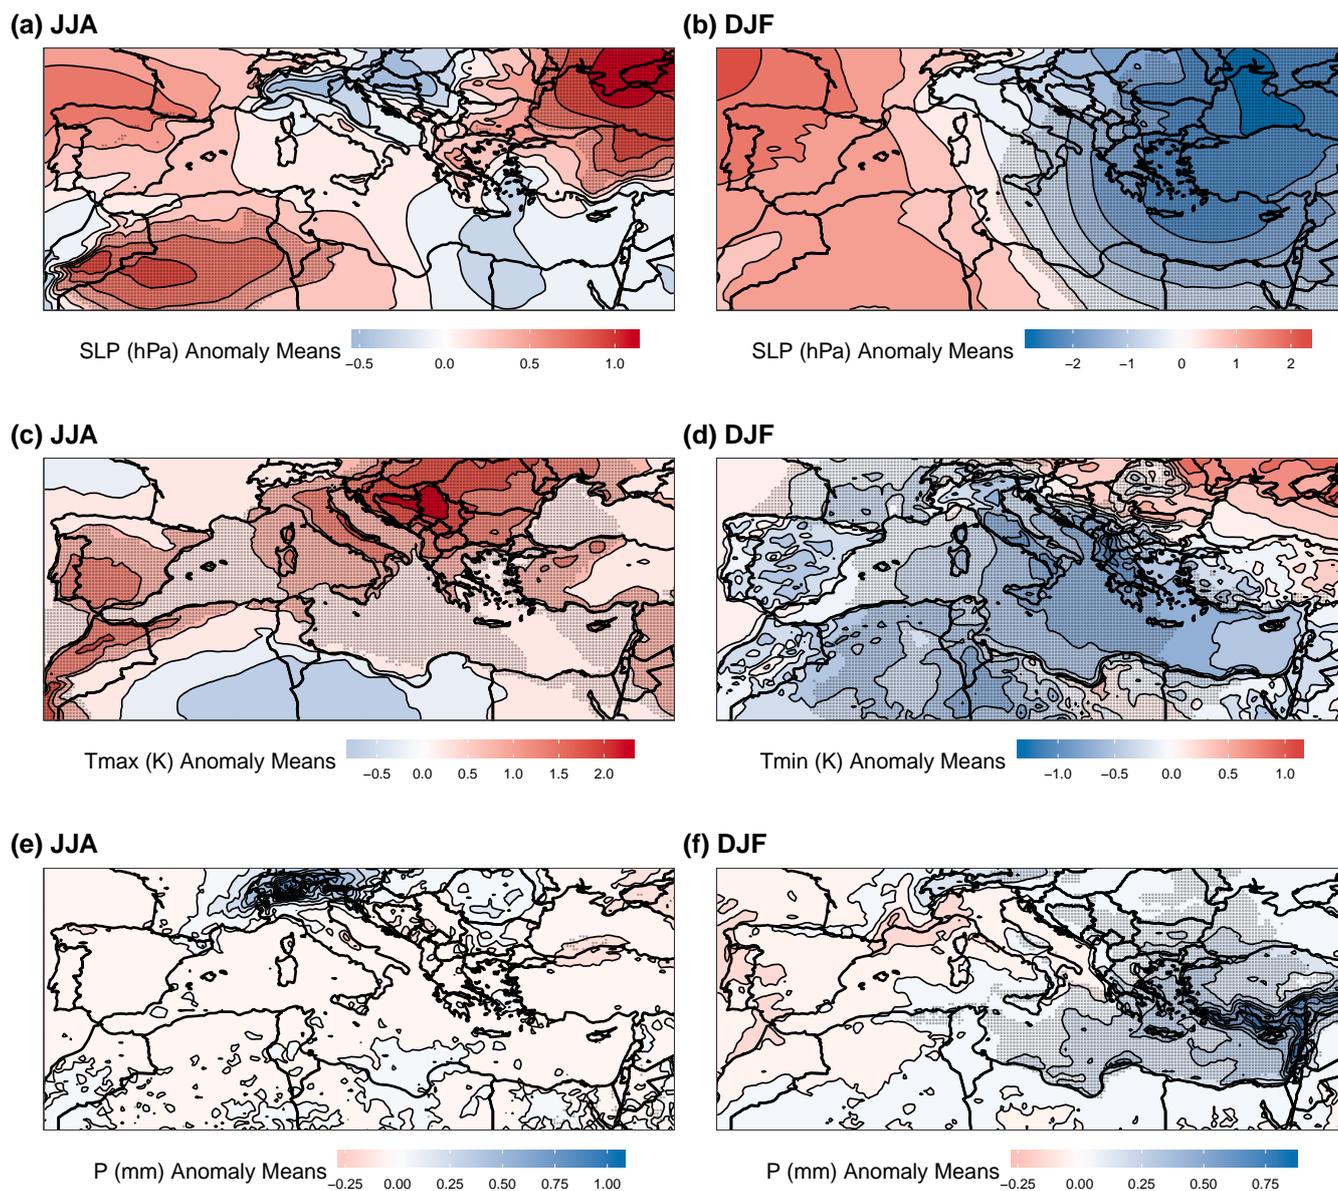

**Figure 3.** Monthly counts of compound dynamical extremes (CDEs) for ERA 5 during 1979-2018 over the Mediterranean. (a)  $\alpha$  computed from Tmax and P; and (b)  $\alpha$  computed from Tmin and P. CDEs are defined as  $\alpha$  daily observations  $> 90^{th}$  quantile of the  $\alpha$  distribution for the full dataset.

## 140 4.2 Pressure, temperature and precipitation anomalies during CDEs

During JJA, CDEs correspond to statistically significant positive SLP anomalies over the western MED (north-western Africa) and the Anatolia - Black Sea region. These are separated by a band of negative SLP anomalies spanning Italy, part of the Balkans, Crete, the Levant and Northern Egypt (Figures 4a and S7a-b). These SLP anomalies are in turn associated with significant warm Tmax anomalies over most of the MED, with a particularly warm Balkan Peninsula, and a negative anomaly  
145 over central northern Africa (Figures 4c and S7c-d). Lastly, we observe weak dry P anomalies over the Black Sea (Figures 4e and S7e-f) and stronger wet P anomalies over the Alps. The latter correspond to statistically significant large-scale P positive anomalies (Figure S8a), rather than convective P anomalies (Figure S8b). This enables us to link these precipitation anomalies to the SLP anomalies discussed above, and in particular to the advection of moist Mediterranean airmasses inland towards the Alpine region. We conclude that JJA CDEs are closely linked to widespread warm Tmax anomalies, but have a weaker  
150 footprint on P anomalies, except over the Alps.

In DJF we observe an east-west dipole in SLP over the MED, that favours cold-air advection from northern Europe to the Italian peninsula, the Balkans, and the eastern MED, leading to significant negative Tmin anomalies in these regions. The eastern MED also displays significant positive P anomalies (Figures 4b,d,f and S9). The statistically significant ( $p$ -value  $< 0.05$ ) negative SLP anomalies over the eastern MED are reminiscent of the footprint of the Cyprus Lows, which are the main  
155 rain-bearing systems over the region (Alpert et al., 2004; Saaroni et al., 2010) (Figures 4b and S9a-b). Cyprus Lows are also associated with the majority of wintertime cold spells over the eastern MED (Hochman et al., 2020), and we indeed find that some of the P anomalies over the eastern MED are snowfall events, particularly over southern Turkey and Lebanon (Figure S10). We thus conclude that CDEs are associated with wintertime cold-wet compound events.

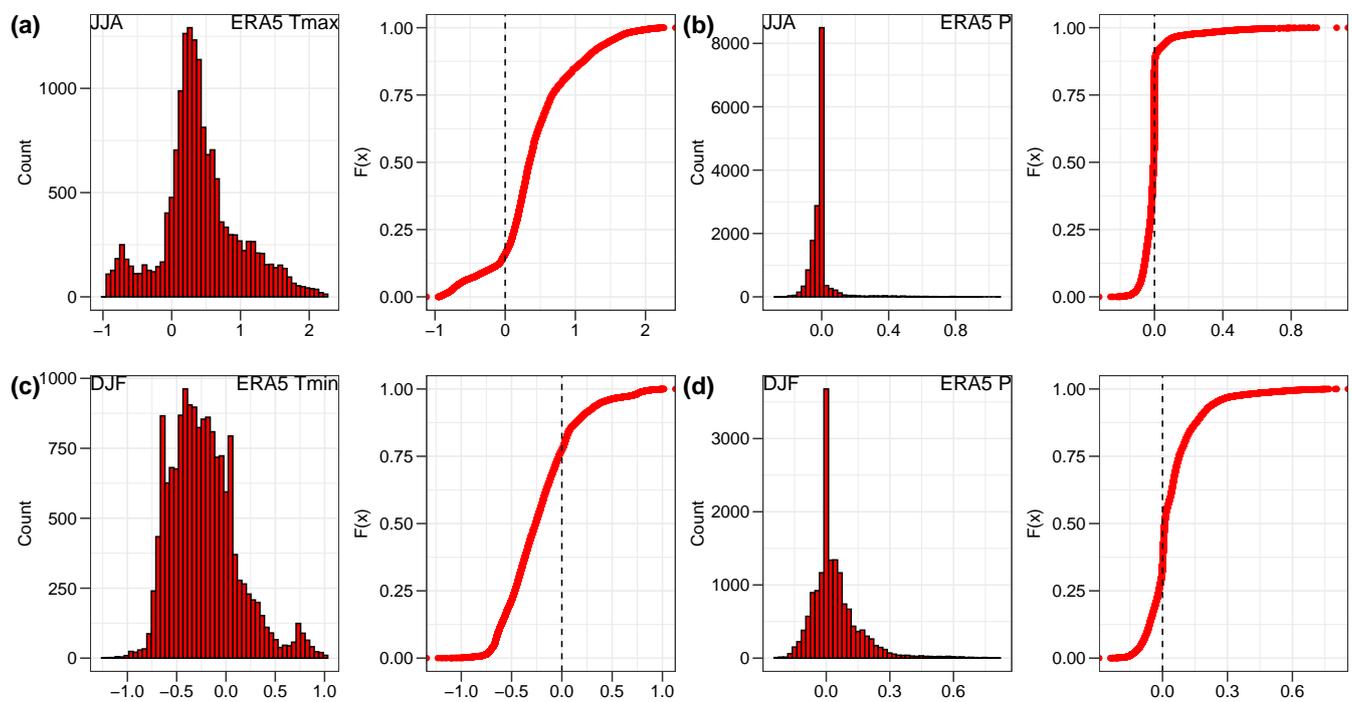

**Figure 4.** JJA and DJF anomaly means of (a-b) SLP, (c-d) Tmax and Tmin, and (e-f) P during CDE days. The data are from the ERA5 reanalysis during 1979-2018.  $\alpha$  for JJA is computed from Tmax and P, whereas for DJF from Tmin and P. Stippling shows statistically significant anomalies ( $p$ -value  $< 0.05$ , Mann-Whitney one-tailed test). The Bonferroni correction is applied to all  $p$ -values.

### 4.3 Distributions of temperature and precipitation anomaly means

160 We next test empirically whether the CDEs highlighted above have a systematic link to compound JJA hot-dry and DJF cold-  
wet events. During JJA, Tmax and P daily anomaly means, computed for each grid-point during CDEs, are predominantly  
hot (84%) and dry (77%) respectively (Figure 5a-b). Similar results are also obtained for ERA-Interim and ERA5 ensemble  
(Figure S11). P anomalies tend to cluster around zero, owing to the overall dry summertime climate of the region, although  
as noted above they do show a preference for negative (dry) values (Figures 5b and S11b,d). A Mann-Whitney one-tailed test  
165 between the anomaly means during CDEs versus all other days in JJA results in statistically significant differences (p-value  
<0.01) for all reanalysis products for both Tmax and P. This implies that CDEs are significantly hotter and drier than other JJA  
days.

In DJF, most of the Tmin and P anomaly means are cold (77%) and wet (66%) respectively for ERA5 (Figure 5c-d) and the  
other reanalysis products (Figure S12). The CDEs therefore present a somewhat mirror image of the preferred anomalies seen  
170 in both JJA and DJF. Again, a Mann-Whitney one-tailed test between anomaly means during CDEs and all other DJF days  
highlights statistically significant (p-value <0.01) differences for all reanalysis products' Tmin and P. This implies that CDEs  
are significantly colder and wetter than all other DJF days.

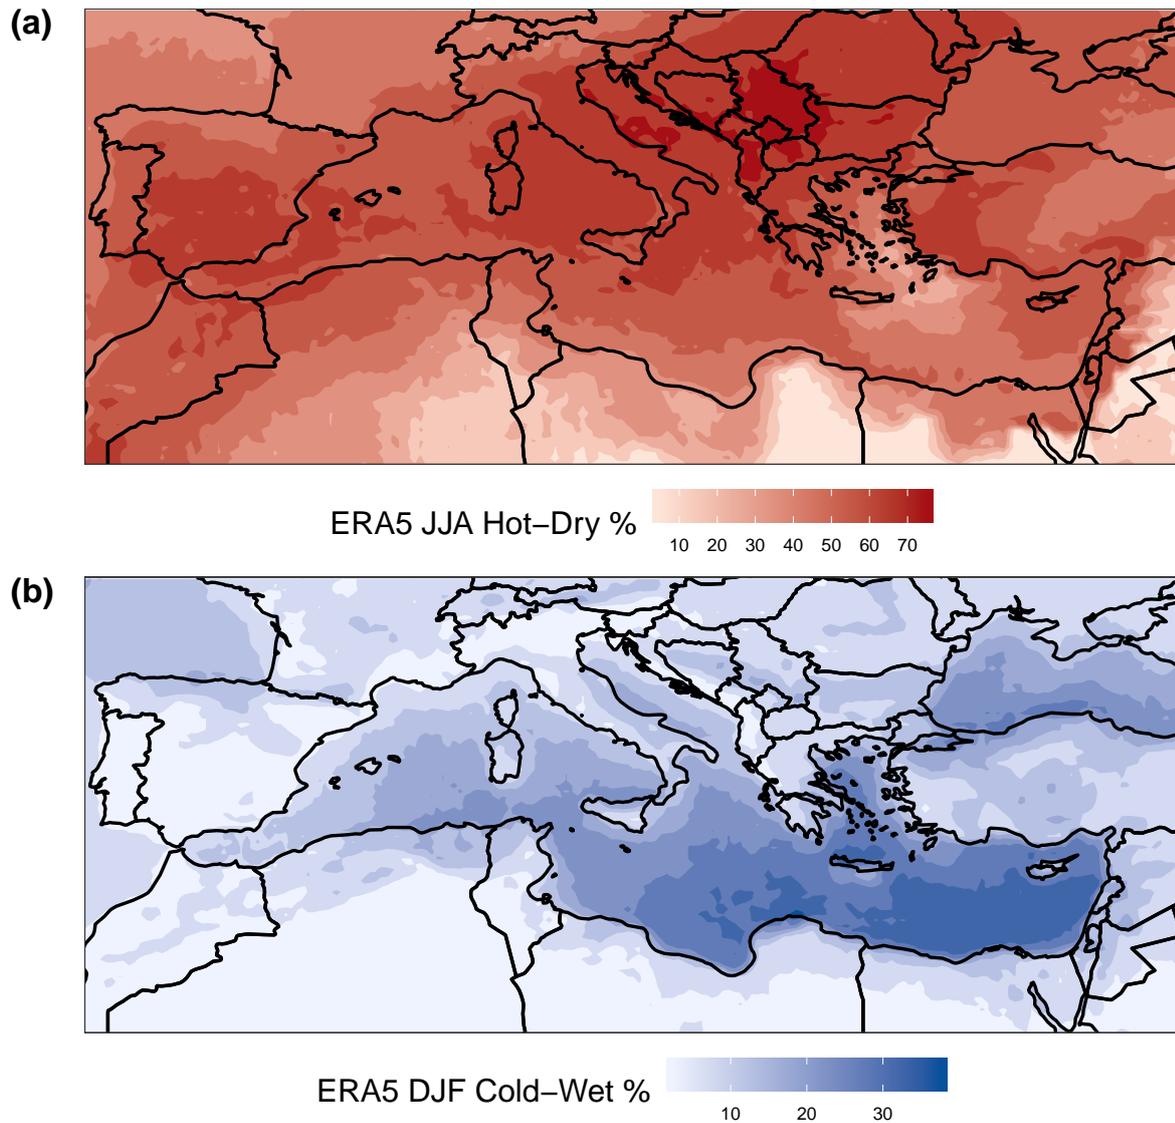

**Figure 5.** Histograms and cumulative distribution functions (CDFs) of anomaly means of (a) Tmax, (b) P during JJA CDEs, and (c) Tmin, (d) P during DJF CDEs. The data are the same as in Figure 4c-f. The distributions are statistically different from those of all other JJA and DJF days, respectively (p-value <0.01, Mann-Whitney one-tailed test).

#### 4.4 Spatial patterns of compound hot-dry and cold-wet events

We next complement the statistical information provided by the histograms and CDFs with spatial distributions of percentage  
175 (%) match between compound events and CDEs. Across the MED, a high fraction of compound hot-dry events during JJA  
coincide with CDEs. Values locally exceed 70%, meaning that >70% of all JJA compound hot-dry events occur during CDEs  
(Figures 6a and S13). The highest percentages occur along a belt stretching from southern Spain to Italy, the central-eastern  
MED and the Balkans. During DJF, the % match between compound cold-wet events and CDEs is lower than that seen for hot-  
dry JJA events (<50%) (Figures 6b and S14). The highest % of compound events occurs over the eastern MED sea, between  
180 the coastlines of Libya, Egypt, Greece and Turkey.

**Figure 6.** Percentage (%) of compound (a) JJA hot-dry and (b) DJF cold-wet events occurring during CDEs. The data are from the ERA5 reanalysis during 1979-2018.

## 5 Discussion and conclusions

In this paper, we analysed compound hot-dry (cold-wet) events during JJA (DJF) over the MED through the lens of dynamical systems theory. We specifically computed a measure of coupling ( $\alpha$ ) between daily maximum temperature (Tmax) and total precipitation (P) during JJA and daily minimum temperature (Tmin) and P during DJF. We then identified days when  
185 the two variables are strongly coupled ( $\alpha > 90^{th}$  percentile of its full distribution) and termed them compound dynamical extremes (CDEs). We further computed a dynamical systems measure of the persistence of large-scale configurations in the above variables ( $\theta^{-1}$ ), considering them both individually and in pairs.

During JJA,  $\alpha$  and  $\theta_{Tmax,P}^{-1}$ , namely the persistence of joint large-scale configurations of Tmax and P, both display significant upward trends. An upward persistence trend is also found if we focus specifically on hot-dry days. We propose these  
190 trends are driven by surface warming over the MED. A possible physical process driving increasing coupling with increasing temperature is soil drying, although we didn't investigate this in detail here. Specifically, the increasingly warm summer temperatures may lead to significantly lower soil-moisture content, triggering a feedback mechanism that favours persistent hot-dry conditions. Consistently with this, we found that CDEs computed from Tmax and P cluster during July and August, whereas CDEs computed from Tmin and P cluster during DJF. During CDE days, synoptic patterns in JJA show significant  
195 positive SLP and hot Tmax anomalies over large parts of the MED, and dry but weaker anomalies for P. The latter is somewhat unsurprising, as the low climatological summertime precipitation over the region effectively prevents the occurrence of large negative precipitation anomalies. In DJF CDEs are associated with significant negative SLP anomalies and cold-wet anomalies centred over the Eastern Mediterranean. The distributions of anomalies occurring during CDEs are significantly different (p-value  $< 0.01$ ) from the ones recorded during all other days. Lastly, we found that CDEs correspond to a heightened frequency  
200 of positive Tmax anomalies during JJA and a heightened frequency of negative Tmin and positive P anomalies during DJF over large parts of the MED. The percentages of cold-wet days during DJF matching CDE days are, however, lower than those found during summer for hot-dry days.

The findings that summertime Tmax and P have become more strongly coupled over the last 40 years, and that the persistence of hot-dry days has increased, are in agreement with Zscheischler and Seneviratne (2017). The latter showed that  
205 land-atmosphere feedbacks in a warmer world may lead to an increase in hot-dry summers larger than what may be expected by analysing the projected temperature and precipitation changes as single variables. Assuming a continued increase in future temperatures, we may therefore expect a continued increase in JJA  $\alpha$  and  $\theta^{-1}$  trends, leading to a higher frequency of compound JJA hot-dry events.

The analysis of DJF CDEs, matching cold-wet events, points to very different dynamics. Here, the largest anomalies in  
210 SLP, Tmin and P are found over the Eastern Mediterranean, and are reminiscent of the footprint of Cyprus Lows. These are wintertime synoptic systems that play a predominant role in driving cold spells and heavy precipitation events over the Levant (Hochman et al., 2019, e.g.). Our findings show no significant increase in  $\alpha$  values during DJF, in accordance with studies

suggesting a decrease in Cyprus Lows frequency, persistence and associated precipitation over the eastern MED (Hochman et al., 2020, 2018; Peleg et al., 2015).

215 Our findings highlight a close connection between CDEs, computed from dynamical systems coupling, and compound hot-  
dry and cold-wet events over the MED. It is of particular interest that  $\alpha$  distinguishes between JJA hot-dry and DJF cold-wet  
compound events. Based on our results we thus believe that the co-recurrence ratio ( $\alpha$ ) may be fruitfully used in forthcoming  
studies to elucidate potential future seasonal climate changes over the MED. We envisage making use of CMIP6 data under  
different Shared Socioeconomic Pathways (SSPs) up to 2100 (O'Neill et al., 2016) and abrupt climate change simulations (e.g.  
220 4xCO<sub>2</sub>) (Eyring et al., 2016). These investigations may also shed some light on possible tipping points over the MED (Lenton  
et al., 2008; Lenton, 2011).

*Author contributions.* PDL designed the study, performed the analyses and created the figures. GM, DF and DC contributed to the methods and study design. PDL and GM wrote the first manuscript draft. All the authors contributed to the writing.

*Competing interests.* The authors declare that they have no conflicts of interest.
