15 **Abstract**

Land-use models and Integrated Assessment Models provide scenarios of land use/cover (LULC) changes following pathways or storylines related to different socio-economic and environmental developments. The large diversity of available scenario projections leads to a recognizable variability in impacts on land ecosystems and the levels of services provided. We evaluated 16 projections of future LULC until 2040 that reflected different assumptions on socio-economic demands and modeling protocols. By using these LULC projections in a state of the art dynamic global vegetation model, we simulated their effect on selected ecosystem service indicators related to ecosystem productivity and carbon sequestration potential, agricultural production and the water cycle. We found that although a common trend for agricultural expansion exists across the scenarios, where and how particular LULC changes are realized differs widely across models and scenarios. They are linked to model-specific considerations of some demands over others and their respective translation into LULC changes and also reflect the simplified or missing representation of processes related to land dynamics or other influencing factors (e.g., trade, climate change). As a result, some scenarios show questionable and possibly unrealistic features in their LULC allocations, including highly regionalized LULC changes with rates of conversion that are contrary to or exceeding rates observed in the past. Across the diverging LULC projections we identified positive global trends of net primary productivity (+10.2%), vegetation carbon (+9.2%), crop production (+31.2%) and water runoff (+9.3%), and a negative trend of soil and litter carbon stocks (-0.5%). The variability in ecosystem service indicators across scenarios was especially high for vegetation carbon stocks ($\pm 4.1\%$) and crop production ($\pm 12.2\%$). Regionally, variability was highest in tropical forest regions, especially at current forest edges, because of intense and strongly diverging LULC change projections in combination with high vegetation productivity dampening or amplifying the effects of climatic change. Our results emphasize that information on future changes in ecosystem functioning and the related ecosystem service indicators should be seen in light of the variability originating from diverging projections of LULC. This is necessary to allow for adequate policy support towards sustainable transformations.

40

1. Introduction

The recently presented IPCC Special Report on Climate Change and Land (IPCC, 2019) highlighted unprecedented rates of land and freshwater use, biodiversity loss, and underpinned existing socio-

45 economic, ecological and climatic challenges such as increasing per capita food consumption, land
degradation and an accumulation of climate extreme events. The IPBES Global Assessment Report
published earlier in 2019 (IPBES, 2019) also reported deteriorating levels of most ecosystem services
(ES) and natural capital due to past and current human activities. The cumulative contribution of land-
use and land-cover (LULC) change to global CO₂ emissions has been estimated to about one third of
50 total anthropogenic emissions since pre-industrial times (Friedlingstein et al., 2019), and total
greenhouse gas emissions from LULC in recent years are nearly 25% of total anthropogenic emissions
(IPCC, 2019). The diversity of current challenges towards a more sustainable use of land, including the
maintenance of critical levels of resources and counteracting climate change, and the various options
to approach these challenges create a large option space for possible future developments of LULC.

55 Future LULC and changes therein are modelled based on initial conditions of land use together with
LULC history and different assumptions about possible socio-economic and environmental
developments regarding population growth, international cooperation, consumption preferences or
technological developments. All of these are represented differently in land-use models (LUM) or
Integrated Assessment Models (IAM, e.g., DeFries et al., 2004; Meiyappan et al., 2014; van Vliet et al.,
60 2016). However, these models play a central role in assessing possible climate change mitigation and
adaptation or conservation strategies in terms of total land demand, investment and maintenance
costs, and direct and indirect socio-economic and ecological effects (e.g., Humpenöder et al., 2014;
Popp et al., 2014; Reilly et al., 2012).

In total, the diversity of models, initial model conditions, socio-economic pathways, processes and
65 process feedbacks considered in the LULC modeling procedure leads to a large number of diverging
land-use projections. This reflects not only the fact that the future is unknown but also a large
uncertainty introduced by the model structure itself (e.g., Alexander et al., 2017; Prestele et al., 2016;
Schmitz et al., 2014; Stehfest et al., 2019; van Vliet et al., 2016). By evaluating a large set of LULC
projections (75 and 43, respectively), Alexander et al. (2017) and Prestele et al. (2016) attributed a
70 significant share of the uncertainty in global and regional LULC projections to the model initial
conditions, resulting in part from different LULC definitions (especially for pastures, see also, e.g.,
Verburg et al., 2011), followed by the model structure, scenario storyline and other factors. Alexander
et al. identified the differences in projected global LULC associated with the modeling approach to be
at least as great as the differences due to scenario variations. In a regional-level analysis, Prestele et
75 al. found the highest uncertainty in land-use projections generally at the edges of boreal and tropical
forests. LULC projections have also been evaluated in a number of model intercomparison studies, in
which models simulated the same scenario storylines based on harmonized drivers, in order to focus
on the uncertainty in LULC changes resulting from structural differences between the models (e.g.,
Von Lampe et al., 2014; Popp et al., 2017; Schmitz et al., 2014; Stehfest et al., 2019).

80 The large uncertainties in LULC projections affect ecosystem functioning globally, which critically
underpins the supply of future ES available to human societies. In the same ways as the effects of
climate change, the uncertainties arising from different LULC projections need to be identified and
understood to adapt ecosystems in a sustainable way and possibly counteract critical regional trends.
Studies have focused on the vulnerability of ecosystems and their services to changes in climate (e.g.,
85 Ahlström et al., 2012; Huntingford et al., 2011; Ostberg et al., 2013; Scholze et al., 2006), land use on
global or regional scale (e.g., Arora and Boer, 2010; Foley et al., 2005; Jantz et al., 2015; Krause et al.,
2017; Lawler et al., 2014; Sterling et al., 2013) and a combination of climate and land-use effects (e.g.,
Dunford et al., 2015; Kim et al., 2018; Krause et al., 2019; Rabin et al., 2020). Also uncertainties arising
from different ES quantification methods were estimated (e.g., Schulp et al., 2014). These studies have
90 already begun to document that diverging LULC projections are as important as diverging climate
change scenarios in the degree of impact on ecosystems.

We expand these previous studies here by bringing together a larger number of LULC scenarios and by
critically examining the resulting variability in the impact of diverging LULC patterns on ecosystems

95 and related ES indicators. We intend to (1) evaluate LULC patterns of LUM projections based on recent
100 historical observations, (2) identify the variability in selected ES indicators arising from diverging LULC
projections, and (3) support the interpretation of conclusions derived from LUMs and IAMs towards
policy decisions for instance on intensification, conservation or climate change mitigation options. Our
basis were 16 projections of future land-use from five LUMs or IAMs with different modeling protocols
and socio-economic pathways. Their scenario storylines span a wide range of worldviews and policies,
with some implemented to achieve a certain climate mitigation or conservation target while others
focus only on basic demands for agricultural commodities, built-up area, etc. Models and scenarios
were assessed based on their underlying demands, modeling protocols (assumptions involved,
allocation strategies, etc.) and the projected spatially explicit land-use futures that they describe. Then,
105 we used the 16 land-use projections as input for simulations with a state of the art dynamic global
vegetation model (DGVM) to analyze their effects on ecosystem functionality and six selected ES
indicators linked to the productivity and carbon sequestration potential of ecosystems (net primary
productivity, vegetation C, soil and litter C), agricultural production (crop production) and the water
cycle (evapotranspiration and annual runoff). We focused on changes until 2040, i.e. the near to
medium future.

110

2. Methods

2.1. Land-use models and scenarios

115 We used a total set of 16 land-use scenarios originating from five different LUMs or IAMs. The models
differ in their underlying demands, modeling protocols and technical aspects (e.g., number of
represented land-use classes, time horizons), which are summarized in the following and in Table 1.
Although some of the models considered here are IAMs including a land-use component, we refer to
all models in this study as global LUMs for the remainder of this paper because their projected LULC
change is the target of this analysis. This includes the two versions of the Land-use Harmonization
(LUH) project prominently applied in many studies of the last and the upcoming IPCC reports, although
120 these land-use products are based on the outputs of several LUMs/IAMs.

The CLUMondo model (van Asselen and Verburg, 2013) applies 30 land system types to model LULC
changes. Land systems define typical combinations of shares of cropland, grassland, bare land and
built-up land together with a specific management intensity (e.g., extensive cropland with few
livestock). Land systems are dynamically allocated based on local suitability, spatial restrictions and
125 the competition between land systems to fulfill demands that were created exogenously by the IMAGE
model on the level of world regions. Trade between world regions is excluded in CLUMondo. Eitelberg
et al. (2016) designed three CLUMondo scenarios: a reference scenario based on FAO-expected
developments of basic demands, and two scenarios that in addition included a policy target of reducing
deforestation and greenhouse gas emissions with a higher ecosystem carbon storage, and
130 international policy targets for the prevention of biodiversity loss.

The Integrated Model to Assess the Global Environment (IMAGE) is an IAM framework including sub-
models representing the energy system, agricultural economy, land-use and the climate system
(Stehfest et al., 2014). LULC allocation is done following an assessment and ranking of land's suitability
to fulfill demands. From IMAGE, a LULC baseline projection following increased food demand and
135 population growth according to the Shared Socioeconomic Pathway (SSP) 2 (O'Neill et al., 2014) is
available and two additional scenarios involving land-based climate-change mitigation, either via the
conservation and expansion of global forest area (ADAFF) or bioenergy crop cultivation and
subsequent carbon capture and storage (BECCS) (Krause et al., 2017).

140 MAgPIE is a global land-use model of the agricultural sector (Lotze-Campen et al., 2008; Popp et al.,
2014). It optimizes spatially-explicit land-use patterns in a recursive dynamic way to satisfy given
commodity demands at minimal production costs while meeting biophysical and socio-economic

constraints. Options to fulfill increasing demands are intensification (yield-increasing technologies), cropland and pasture expansion and international trade. Future land-use projections of the MAGPIE model follow the same storylines as described for IMAGE (Krause et al., 2017).

145 The Hurtt et al. (2011) modeling approach (LUH1) combines a historic land-use reconstruction with national statistics of historical wood harvest and assumptions regarding shifting cultivation in some tropical regions and harmonizes these data with a set of four future LULC scenarios. Each scenario was produced by a different IAM with each individual demands and strategies for allocating LULC in response to the demands. The four scenarios follow very different socio-economic storylines that are
150 combined with the emissions and climate change assumptions of the Representative Concentration Pathways (RCPs). LUH1 scenarios are not tied to the SSPs as these were only introduced in 2014. These scenarios have frequently been used in the modeling community, especially for the work in the IPCC AR5 (e.g., O'Neill et al., 2014; van Vuuren et al., 2014). We used here the version of LUH1 which had the historical dataset extended until 2014 (Le Quéré et al., 2015), and future trajectories following IAM
155 implementations of RCPs 2.6, 4.5, 6.0 and 8.5.

The Land Use Harmonization v2 (LUH2; v2.1, Hurtt et al., 2020) has been developed for the CMIP6 intercomparison project (Eyring et al., 2016). It follows a similar methodology as in LUH1, but on a higher spatial resolution and a longer time domain, using updated historical land-use reconstructions along with updated models of past and future land transitions and management (e.g., wood harvest,
160 crop rotations and shifting cultivation) and extending the number of scenarios by combining RCPs with the SSPs. Similar to LUH1, future LULC transitions in LUH2 are based on land-use projections from different IAMs each following an own strategy for allocating LULC in response to demands. Of the eight scenarios that have been harmonized in LUH2 with historical data, three scenarios were selected (SSP1-26, SSP3-70, SSP5-85) to span the range from low to high radiative forcing as in the LUH1
165 scenarios in combination with diverging land-use trends according to the SSPs.

2.2. LPJ-GUESS model

The process-based dynamic global vegetation model LPJ-GUESS simulates vegetation dynamics in response to climate, atmospheric CO₂, land-use change (Lindeskog et al., 2013) and nitrogen (N)
170 dynamics (Olin et al., 2015; Smith et al., 2014). Three distinct land-use types are represented (natural vegetation, pasture and cropland). Vegetation dynamics on natural areas are characterized by the establishment, competition and mortality of twelve plant functional types (PFTs, ten woody and C3 and C4 grass types, as in Smith et al., 2014), which are distinguished in terms of their bioclimatic preferences, photosynthetic pathways and growth strategies. Pastures are populated with competing
175 C3 and C4 grass PFTs, where each year 50 % of the above-ground biomass are removed as a representation of grazing (Lindeskog et al., 2013). Croplands are represented by prescribed fractions of crop functional types (CFTs, i.e. C3 crops with winter and spring sowing date, C4 crops and rice), with crop specific processes including dedicated carbon allocation and phenology, explicit sowing and harvest representation, irrigation, fertilization and unmanaged cover grass growing between cropping
180 seasons (Olin et al., 2015). Crops are prescribed to be either rain-fed or irrigated (Lindeskog et al., 2013). LPJ-GUESS does not assume yield increases due to technological progress (such as advanced new varieties, management techniques, pest control), but yields respond to changes in climate, atmospheric CO₂ concentration, N input (deposition and fertilizer rates) and the fraction of rainfed vs. irrigated cropland. Adaptation to climate change is partially accounted for by a dynamic calculation of
185 potential heat units (PHU) needed for the full development of a crop before harvest, simulating the adequate selection of suitable crop varieties under changing climate (see Lindeskog et al., 2013). Upon conversion of forested natural land for agriculture, 20% of the woody biomass enters a product pool (turnover time of 25 years), with the rest being directly oxidized (74 %) or decomposed as litter (6 %). Following agricultural abandonment, natural vegetation recolonizes the land in a typical succession

190 from herbaceous to woody plants, with competition for resources and light among age cohorts of
woody PFTs simulated directly through forest gap dynamics.

2.3. Simulation setup

195 LPJ-GUESS was run at $0.5^\circ \times 0.5^\circ$ resolution forced by monthly climate of the IPSL-CM5A-LR general
circulation model (GCM) driven by RCP 2.6 concentrations for the future period. The model projects
a global average surface temperature increase of about 1.3°C by the end of the century relative to
1980-2009, which lies in the middle of an ensemble of a wider range of GCMs used in the ISI-MIP
intercomparison project (Warszawski et al., 2014). Table S1 provides the detailed simulation set-up
with all forcing data for the LPJ-GUESS simulations. Effects of differences in the modeling protocol of
200 CLUMondo/LUH1/LUH2 and IMAGE/MAGPIE simulations for projections of ecosystem dynamics affect
especially the base level of ES indicators in 2000-2004 and the relative deviations over time, which this
study is focused on, only to a small degree. Therefore, we don't expect these differences to impair the
results of this study and the conclusions drawn to a significant degree.

LULC fractions were taken as net annual transitions from the LUMs and aggregated to the three land
205 use types cropland, pasture and natural used by LPJ-GUESS and to the spatial resolution of $0.5^\circ \times 0.5^\circ$
if needed. For CLUMondo, regional fractions of the three land use types for each land system were
used. Cropland and pasture fractions were directly adopted from LUMs, with cropland also including
bioenergy areas and pasture including rangeland and grazing land. All classes related to natural land
were merged (forest, primary land, secondary land, other natural, degraded forest). As LPJ-GUESS
210 doesn't represent urban land, built-up areas are also included in the natural land fraction. Where 0.5°
gridcells contain substantial shares of water, this fraction was assigned to bare land, i.e. excluded from
the simulation of vegetation pattern in LPJ-GUESS. We modeled the ice-free land surface and included
only those grid cells in our simulations for which all LUM provided data. LUM data were not processed
e.g. to harmonize to a common historical period or to align parts of the modeling process, but in each
215 simulation run there was a seamless transition from historical to future, which is needed to simulate
vegetation and carbon cycle responses. A sensitivity experiment to explore the range of variability due
to different climate models was run using the RCP 2.6 outputs from GFDL-ESM2M, HadGEM2-ES,
MIROC-ESM-CHEM and NorESM1-M models (Warszawski et al., 2014) and LULC from the four LUH1
scenarios.

220

2.4. Simulation of ecosystem service indicators

Changes in ecosystem function and services were assessed using a suite of regulating and provisioning
ES indicators: net primary productivity (NPP, foremost an indicator for ecosystem productivity and
carbon sequestration related to global climate regulation, also used as indicator for ecosystem health),
225 C storage (natural capital that underpins and is closely related to carbon sequestration and global
climate regulation), crop production (contributing to food supply), annual water runoff (indicator for
water availability but also related to flood regulation) and evapotranspiration (indicator for regional
climate regulation). C storage was investigated for vegetation, soil and litter C and total C with the
latter also including carbon stored via CCS in BECCS scenarios. All variables are direct outputs of LPJ-
230 GUESS simulations. Crop yields of each simulation were scaled to FAO observed yields in 1997-2003 as
in Krause et al. (2017). Changes in ES indicators were analyzed for each LULC scenario as % change in
2036-2040 relative to the base level in 2000-2004. The average of 5 years was used to reduce the
influence of inter-annual variability. Since climatic and atmospheric changes are identical across the
simulations, differences in ES indicator changes across the scenarios reflect mostly the immediate and
235 long-term effects of changes in LULC, also taking into account that climate change impacts might be
dampened or amplified depending on the vegetation cover existing in a grid location. The evaluation

of percent changes in future LULC and ES indicators relative to the baseline period in 2000-2004 partially takes account of differences in baseline LULC patterns and ES provision levels across the scenarios.

240

3. Results

3.1. Strategies of LU models to translate demands into land use changes

Fig. 1 and 2 summarize LULC changes of the 16 projections. The scenarios projected total changes in LULC of about 4.5% to 11.4% of the global ice-free land surface from 2000 to 2040 (Table S2), corresponding to different transitions between crop, pasture and natural land. While different socio-economic assumptions realized as land-use change projections by the same model led only to small variations in the outcomes in terms of absolute rates (see Fig. 1, Table S2) and spatial patterns of LULC changes (see Fig. 2), the variation in land-use change between models was much more important, including for similar socio-economic scenarios. This highlights the importance of the differences in modeling strategies. In this regard, we realize that the outcomes as described are indicative for the model's behaviors for the particular scenarios considered in this study, which are not necessarily but very likely representative for the model's general behaviors upon projecting future LULC patterns. LUH1/2 are exceptions in regard to the changes in between scenarios because individual scenario data originate from different LUMs, therefore their data differ substantially between all scenarios.

245

250

In comparison to the other LUMs, CLUMondo shows rather small-scale LULC changes spread across large parts of the world (Fig. 2). In CLUMondo, LULC changes are occurring not between land cover types but between more complex land use systems that have different compositions in terms of land cover (e.g., from land use mosaics with a high fraction of natural vegetation to land use mosaics with less natural vegetation). In order to compare these changes with other model's outputs, we converted land system information into changes between cropland, pasture and natural land (see method section). The three scenarios have the same demands for livestock, crop production, etc. and the additional objectives in terms of carbon uptake and storage or biodiversity conservation did not introduce large variations. Therefore, differences between the CLUMondo scenarios are small (see Table S2). The biodiversity scenario leads to most land area changes due to land system classes that diverge to either system intensification in some regions or extensification in others. Demands are fulfilled by almost linear trends until 2040 based on the assumed scenario storyline and demand estimates (Fig. 1).

255

260

265

Land-use changes in the three IMAGE scenarios also affected most of the productive land areas globally. Compared to CLUMondo, spatial patterns are different and the spread of percentage area changes across scenarios was higher (globally 5-10% difference per LULC class for IMAGE scenarios, see Table S2). Global trends are not linear; some scenarios even reverse their historic trend (e.g., IMAGE_ADAFF scenario for pasture) or accelerate it (e.g., IMAGE_BECCS scenario for cropland), possibly driven by the introduction of new land-use policies. In IMAGE, demands targeting food production and therefore affect cropland and pasture changes directly are modelled with higher priority. The Base scenario accordingly increases pasture area at the cost of natural land (presumably to satisfy demand for animal products in the underlying "SSP2" world) while cropland increases only slightly, presumably because yield increases satisfy the increasing food demand of a growing population. The afforestation and reforestation scenario IMAGE_ADAFF partially reverses IMAGE_Base by expanding natural land at the cost of pasture land, while IMAGE_BECCS in addition to pasture expansion as in IMAGE_Base also expands cropland areas at the cost of natural land. Spatially, the distribution of land-use classes among all scenarios differs little, indicating that demands from the base scenario (e.g., population growth, food demand, trade) outweigh specific scenario demands.

270

275

280

In MAgPIE, land changes only occur in specific regions or countries, but then massively (SE Argentina and Southern Brazil, some countries in Eastern Africa and parts of Southern and Eastern Asia), with the by far dominant change being cropland expansion. The three MAgPIE scenarios differ relatively little in time and space, only the afforestation and reforestation scenario shows some again very local natural area expansion. Trends over time are linear. Decisions of where land use change takes place to meet food and feed demand strongly depend on minimising the costs of land conversion. Here, some countries seem to provide substantially cheaper commodity prices than others, explaining the radical changes seen in some countries or regions. Noteworthy, MAgPIE and IMAGE derive potential crop yields and ecosystem C densities from the same DGVM (LPJmL, Bondeau et al., 2007), even though internal yield scaling and forest growth curves are implemented differently. However, their spatial patterns are quite different, emphasizing the role of individual strategies to translate demands under similar biophysical constraints into LULC patterns. Also the land demand to meet the same CDR target was found to be larger in IMAGE than in MAgPIE (Krause et al., 2018).

In contrast, land changes in all LUH1 scenarios are large and occur in most of the productive land areas globally, reflecting both the highly diverging socioeconomic storylines as well as their implementation by different IAMs (see Table S2). Trends over time are non-linear but involve multiple break points or gradual slopes. Interestingly, LUH1_26Be, which was developed by the IMAGE model (Hurt et al., 2011), focusses on a broad expansion of croplands in tropical regions, while IMAGE_BECCS (however, most likely implementing a different degree of bioenergy growth), includes a massive re-location of pastures and also croplands to tropical and subtropical areas, respectively (Fig. 2). LUH1_45Aff and even more so LUH1_60Stab focus on massive expansion of natural areas in all global regions where forests can be sustained, while LUH1_85Pop expands pastures and secondarily croplands in tropical and subtropical areas. The attribution of specific spatial LULC patterns to model allocation strategies vs. scenario storylines is impossible for LUH1, and in the same way also for LUH2, because underlying IAMs and storylines differ between each scenario.

LUH2 scenarios also differ substantially, corresponding to the very different SSP storylines and RCPs combined with their origin from different IAMs. LUH2s SSP1-26 (also implemented by IMAGE IAM but with different socioeconomic assumptions than IMAGE_BECCS and LUH1_26Be), which includes options for both bioenergy crops and forest regrowth shows expansion of natural areas mostly in temperate (and some boreal) regions of the northern latitudes and also in Australia, some cropland expansion and a reduction in pastures (Fig. 1,2). LUH2_SSP3-70 in contrary results in a massive cropland expansion in some regions, in combination with a re-location of pastures, while LUH2_SSP5-85 (implemented by REMIND/MAgPIE) shows very large and concentrated regional dynamics, with cropland expansion similar to the MAgPIE scenarios as presented above.

In summary, most scenarios only agreed on a trend for cropland expansion at the cost of natural or pasture areas in terms of total area (see also Fig. 1). Moreover, the scenarios showed very diverse patterns on where and how these changes were realized. The deviation in LULC changes from 2000-2004 to 2036-2040 across the scenarios (Fig. S1) therefore showed major disagreement for cropland, pasture and natural areas. Standard deviations of changes in land area >20% were found for all three LULC classes over wide world regions, especially in SE South America, entire sub-Saharan and Eastern Africa and some regions in Europe and Southern Asia. This agreed in parts with features that were identified in earlier studies evaluating a set of multiple model LULC projections, such as in terms of global and regional trends (Schmitz et al., 2014) and the location of hotspots of uncertainty in LULC projections (Prestele et al. 2016). Given the diversity in socioeconomic storylines and land-use models, these findings are not surprising, but highlight (1) the need to critically reflect on which of the observed LULC change patterns might be considered more or less realistic given historical regional developments in combination with environmental, economic and political constraints such as water availability, yield

330 gaps and governance issues, and (2) the need to explore the existing uncertainty in terms of future
LULC regarding the implications for ES indicators beyond yields.

3.2. Ecosystem service indicators for alternative LU scenarios

The 16 land-use scenarios resulted in very diverse levels of ES indicators in 2000-2004 and changes
therein until 2036-2040 simulated with LPJ-GUESS (see Fig. 3 and Tab S3 for all results given in the
335 following). Fig. 4 shows the spatial distribution of categories in ES indicator levels and their changes
until 2036-2040, averaged across the 16 scenarios. We decided to also investigate averages to explore
some overall emerging trends in ES indicators that result from the combined effects of climate and
land-use change on ecosystem functionality. The average maps are complemented by the regional
variability in ES indicators (right maps in Fig. 4, see also section 4.2) as a measure for the large between-
340 scenario variability in ES indicators. Where regional variability is low, differences in LULC across
scenarios are small and ES indicator changes can solely be attributed to climatic changes and/or
changing CO₂ concentration.

The declining trend in natural areas (average decline of $0.9\% \pm 4.0\%$ by 2036-2040 across 16 scenarios)
as shown by most LUMs (Table S2) is balanced by the combined positive effect of increased
345 atmospheric CO₂ concentrations, N deposition and warmer climate (especially in higher latitudes)
leading overall to an increased global vegetation productivity ($+10.2\% \pm 1.4\%$) and higher total C stocks
($+1.4\% \pm 1.1\%$) across the scenarios. Simulated changes agreed in the trend but levels were below
those reported in previous studies (compare LPJ-GUESS simulations including LULC changes for IPSL-
CM5A-LR climate of Brovkin et al., 2013; Pugh et al., 2018), noting that these studies applied different
350 LULC data and used LPJ-GUESS without C-N limitation and with differing model set-up. Regionally,
increases in vegetation productivity and C stocks were pronounced in boreal and temperate forests,
while in the tropics, positive effects of especially CO₂ fertilization and improved water use efficiency
(see, e.g., Wårlind et al., 2014) were reduced by cropland and pasture expansion, jointly with negative
effects of warmer and drier climate. Across the 16 scenarios, the increase in NPP and C storage was
355 generally higher in CLUMondo, LUH1 and LUH2 than in IMAGE and MAgPIE scenarios. Increases in
vegetation and total C stocks were, as expected, large in scenarios that showed significant amounts of
forest regrowth (especially LUH1_45Aff, LUH1_60Stab, LUH2_SSP1-26, but also IMAGE/MAgPIE_ADAFF)
and low in scenarios with agricultural expansion for food (e.g., IMAGE_Base, LUH1_85Pop) or
bioenergy production (IMAGE/MAgPIE_BECCS, LUH1_26Be). The overall changes in
360 total C stocks reflected an increase in vegetation C ($+9.2\% \pm 4.1\%$) that was balanced to some degree
by a decrease in soil and litter C stocks ($-0.5\% \pm 0.4\%$), likely driven by enhanced respiration of organic
material under warmer temperatures (see, e.g., Pugh et al., 2015), in combination with the negative
effects of decreasing natural areas on soil and litter C in most scenarios. The simulated increase in
vegetation C was significantly lower and the decrease in soil and litter C larger for all IMAGE and
365 MAgPIE scenarios because in these scenarios, the conversion of natural land to pastures (for IMAGE)
and to croplands (for MAgPIE) was largest among the analyzed scenarios.

Crop production was simulated to increase on average across all 16 scenarios by $31.2\% \pm 12.2\%$ partly
as a result of total cropland area increasing ($+11.7\% \pm 10.5\%$, Table S2) for all scenarios except in
LUH1_45Aff, and partly due to increasing yields. Yield increases resulted from the joint effects of
370 increased N fertilization rates, warmer temperatures in some regions and increasing atmospheric CO₂
(relative importance of the three factors, see, e.g., Krause et al., 2017). Crop production increases were
found in all world regions, especially southern and eastern Asia, middle and southern Africa, SE South
America and cropping regions in North America and Europe. Differences in crop production between
scenarios were due to different absolute area and the location of cropland expansion on the globe
(and differences in N fertilization rates for IMAGE and MAgPIE scenarios, see methods). For
375 LUH1_45Aff, the simulated global total increase in crop production was only 2.6% because of the
immense amounts of natural area expansion in this scenario reducing total cropland area in contrast
to the other 15 scenarios. Furthermore, LUH1_60Stab and all IMAGE scenarios showed lower increases

380 than the other scenarios due to only small cropland expansion (in case of LUH1_60Stab) and newly
established croplands being chiefly located in low to medium production areas (in case of IMAGE
scenarios, e.g., Sub-Saharan and northern Africa, Middle East). For all LUH2 scenarios, crop production
increases were high with about 44% relative to the level in 2000-2004. Lower crop production was
simulated in IMAGE and MAgPIE climate change mitigation scenarios in comparison to their baseline
scenarios and also in CLUMondo scenarios when additional land-demands had to be met in comparison
385 to their FAO reference scenario. This highlights the inherent trade-off created through multiple
demands. It has to be noted that IMAGE (and therefore also CLUMondo because its demands are
created by IMAGE) and MAgPIE internally calculate further technology applications (for example
improved management, enhanced fertilizer inputs, pest control and better crop varieties) to increase
yields in mitigation scenarios up to the level of their baseline simulation. However, these are not fully
390 captured by LPJ-GUESS (see methods).

Annual water runoff was simulated to increase on average by $9.3\% \pm 1.7\%$ until 2036-2040 (ranges and
average trend are similar to estimates from Elliott et al., 2013 based on ten global hydrological models).
The increase resulted from the combined effect of increasing global total precipitation (+5.1% from
2000-2004 to 2036-2040 in the IPSL-CM5A-LR model), the increased water use efficiency under
395 elevated CO₂ levels (see, e.g., De Kauwe et al., 2013; Qiao et al., 2010) and changes in the water use of
agricultural vs. forested areas that were shown in many studies (such as reduced evapotranspiration
of croplands in comparison to forests, see, e.g., Farley et al., 2005; Sterling et al., 2013). All these effects
are captured by LPJ-GUESS (e.g., Krause et al., 2017; Rabin et al., 2020). Increases in runoff were
simulated in the temperate zone and higher northern latitudes and in smaller regions in the tropical
400 and subtropical zone. In water limited regions such as the subtropics, some of this water could in
principle be available for irrigation, depending greatly on the regional annual runoff dynamics. But it
will also increase erosion of soil and nutrients (e.g., Salvati et al., 2014) and the risk for floods in some
regions (see, e.g., Rabin et al., 2020), likely also intensifying regional dependencies of water availability
and usage that are discussed elsewhere (see, e.g., Elliott et al., 2013; Fitton et al., 2019). Differences in
405 runoff levels in 2000-2004 and changes until 2036-2040 were small between the 16 scenarios because
the forcing climate dominates the calculated water balance, rather than LULC changes. Only for the
three LUH2 scenarios, about 5% lower absolute levels compared to the other scenarios were simulated
in 2000-2004 and relative increases in runoff were about 3% larger for IMAGE and MAgPIE scenarios
than the other scenarios.

410 Changes in evapotranspiration are closely linked to the calculations of runoff, although their effects
are opposed, with higher evapotranspiration rates contributing to reduced surface runoff (e.g., Piao et
al., 2007), but also to biophysical cooling (e.g., Anderson et al., 2011). Evapotranspiration rates
increased in CLUMondo, LUH1 and LUH2 scenarios on average by $2.6\% \pm 0.3\%$ and decreased in the
IMAGE and MAgPIE scenarios on average by $-0.7\% \pm 0.5\%$. Increases in evapotranspiration rates in
415 non-tropical regions likely reflect the expansion of forests (see, e.g., Sterling et al., 2013) and therefore
were highest in the scenarios assuming intensive expansion of natural areas (LUH1_45Aff,
LUH1_60Stab). This trend was balanced in the three IMAGE scenarios by the effects of large-area
conversion of forests to pastures in tropical South America and Africa leading to a total reduction in
evapotranspiration rates. BECCS activities seem to reinforce the reduction in evapotranspiration rates,
420 while the extension of natural areas counteracts it to about 50%. In MAgPIE scenarios, a strong
increase in cropland area in SE South America and Eastern Africa corresponded with a small overall
decrease in evapotranspiration.

4. Discussion

425 4.1. Projected global land-use patterns in a historical context

(1) Global change rates. The 16 scenarios project total changes in LULC of between 4.5% and 11.4% of the global ice-free land surface from 2000 to 2040. These rates are of a magnitude comparable to those observed for the past. For instance, four historical LULC reconstructions for the period 1960-2000 estimated changes in LULC of 7.5%-12.8% (Hurtt et al., 2011; Klein Goldewijk, 2016; Klein Goldewijk et al., 2011; Ramankutty et al., 2008, see Table S4). A more recent global historical LULC change reconstruction by Winkler et al. (in prep.) estimated net LULC changes of 13.8% for 1960-2015. This reconstruction uses a data-driven approach that is strongly based on remotely sensed information and provides higher spatial, temporal and thematic resolution than previous reconstructions. For a shorter time-period, Liu et al. (2018) based on the ESA CCI Land cover product identified 3.4% net LULC changes for 1992-2015. The picture becomes more complex when gross transitions, rather than net transitions, are considered, since gross changes (e.g., from forest to cropland in parts of a grid location and cropland to forest in another, over one time-step) can be substantially larger than the net change. For instance, change rates of Winkler et al. are 36.4% when gross and multiple LULC changes are being considered individually. By contrast LUM projections have simplified representation of these more realistic LULC dynamics, omitting short-term, two-directional or small-scale transitions (e.g., such as under shifting cultivation, e.g., Heinemann et al., 2017). The improved representation of gross land-use changes in historical and future LULC reconstructions would be an important development to better account for LULC dynamics and their impacts on ecosystems (e.g., Bayer et al., 2017). However, such efforts are still hampered by a limited process understanding and data availability at the global scale.

(2) Future regional change rates in a historical context. Scenarios projecting future demands under reference or business-as-usual assumptions (CLUMondo_FAOref, IMAGE/MAGPIE_Base) are expected to continue recent historic LULC trends at least during the first part of the simulation period. Nevertheless, economic growth assumptions, demographic considerations and limitations in land availability in the scenarios will likely cause some divergence from historical LULC trends. Historic trends are indeed continued in some of the broader regional projected trends, such as the expansion of natural areas in mid to high northern latitudes (CLUMondo_FAOref, IMAGE_Base, see Fig. 2) or the expansion of croplands in subtropical areas (CLUMondo_FAOref, to some degree also IMAGE/MAGPIE_Base) (e.g., Hansen, 2013). In contrast, some projected LULC changes have no historic precedent, such as the extensive pasture increase in tropical Africa (IMAGE_BASE), the large cropland expansion in some selected African countries (MAGPIE_Base), or cropland expansion in Mediterranean and Middle East (IMAGE_Base).

Scenarios including more drastic changes in the socio-economic system (e.g., all LUH1 and LUH2 scenarios), including specific conservation measures or large-scale land-based climate change mitigation efforts (e.g., CLUMondo_CStor/Bdiv, IMAGE/MAGPIE_ADAFF/BECCS) affect future LULC patterns in very different ways, compared to reference or business-as-usual scenarios. Whether or not simulated abrupt LULC changes or a rapid reversion of regional historic LULC trends are realistic is difficult to judge, as analogous historical evidence is scarce or absent. Indeed, some rapid land-use changes have occurred in the past, caused by unexpected disruptions in markets or governance structures (e.g., Brazil's soy moratorium, e.g., Gibbs et al., 2015, collapse of the Soviet union, e.g. Hostert et al., 2011). However, capturing such unexpected LULC changes in global LUM projections is nearly impossible. Still, in response to most policy interventions, work has suggested that transitions in land use across regions tend to occur rather smoothly and with time lags of years to few decades (i.e. spanning a notable part of our simulation period) due to delayed policy uptake (e.g., Brown et al., 2019). In this context, large-area, and relatively rapid regional change rates could be assessed critically, such as (1) forest regrowth on pasture and cropland areas with more than 40% area change from 2000-2004 to 2036-2040 in SE South America (LUH1_45Aff) or entire subtropical Africa (LUH1_60Stab), (2) massive cropland increases exceeding 40% total area change, e.g., in SE South America and eastern Africa (MAGPIE_ADAFF/BECCS and LUH2_SSP5-85), and (3) pasture expansion exceeding 20% of the

total area in tropical and subtropical Africa (e.g., IMAGE_BECCS, LUH2_SSP3-70). The first example
475 reverses current deforestation trends (compare, e.g., Curtis et al., 2018; Hansen et al., 2013), while in
the latter two examples, simulated rates of change are substantially larger than observed in these
regions in recent decades (e.g. Hansen et al., 2013; Klein Goldewijk, 2016, compare Fig. S3). LULC
scenarios assuming significant amounts of forest regrowth, should also be seen in light of the recent
evidence provided by Holl and Brancalion (2020), pointing out manifold problems attached to tree
480 planting and therefore calling for the prioritization of natural forest protection.

(3) Regional LULC allocations. In general, CLUMondo and IMAGE were more capable of capturing
small-scale changes within heterogeneous regions. Given the complexity in which land changes are
being observed (e.g., Curtis et al., 2018; Hansen et al., 2013), the capacity to simulate changes at small
scale is likely more realistic. By contrast, regional patterns in other LUMs tended to be fairly broad in
485 extent or were limited to regions that were small in area. This is not consistent with what can be
learned from global multi-temporal remote sensing.

When assessing the plausibility of regional LULC allocations, a good indicator is the expansion of
agricultural areas (e.g., Salmon et al., 2015) based on existing yield potential (i.e. fertile areas currently
not used or with a low share of croplands) or based on existing yield gaps (i.e. because of poor
490 management or limits posed by the socio-economic environment). We find that the LUMs use the
regions with existing yield capacities in different ways for their allocation of LULC types. Cropland areas
with currently relatively large yield gaps, such as in Brazil's Cerrado, west or east Africa (e.g., Mueller
et al., 2012), were used by CLUMondo for further cropland expansion, which seems plausible also
considering past LULC trends and continuing economic growth in response to an increasing population
495 in these regions. In IMAGE simulations (especially IMAGE_Base/BECCS), these regions were typically
converted into pastures and instead croplands in IMAGE were expanded in northern Africa and
western Asia (especially Syria and Iraq). Besides current political turmoil in north Africa and west Asia,
these allocations seem less plausible considering rather unfertile soils and existing yield gaps that are
predominantly linked to low fertilizer inputs and water scarcity (e.g., Pala et al., 2011). In addition, the
500 expansion of cropland area in IMAGE in northern Africa (especially Libya and Egypt, see Fig. 2) notably
exceeds current cropland extent (e.g., Fritz et al., 2015). It seems doubtful whether this can be indeed
achieved, given that existing yield potential in these regions is low due to biophysical limitations during
the crop-growing season which is not projected to change in the future. Other examples where LUMs
diverge notably include central India, where all IMAGE scenarios used areas with large yield gaps as
505 indicated by Mueller et al. (2012) for cropland expansion. In contrast, all CLUMondo scenarios used
these croplands for forest regrowth, thus ignoring their potential to contribute to fulfill increasing food
demand. The massive, but very regional, cropland expansion of all MAgPIE scenarios and LUH2_SSP5-
85 includes regions in eastern Africa, where yield gaps are high, but also regions in SE South America
that are already under cropland usage to a high degree and attained yields are high (e.g., Fritz et al.,
510 2015; Mueller et al., 2012). This suggests that in the MAgPIE model, economic considerations dominate
the allocation of LULC classes rather than existing biophysical capacities. Only few scenarios (e.g.,
LUH1_26Be, LUH2_SSP1-26, LUH2_SSP5-85) expand cropland area in continental eastern Europe,
especially along the "Chernozem-Belt" into Russia, where soils are fertile and closing yield gaps would
be expected to lead to large returns in terms of enhanced productivity (see Mueller et al., 2012). Other
515 scenarios saw no potential for cropland expansion in these regions and simulated forest regrowth.

It has to be noted, that in regions, where attained yields are relatively close to potential yields already
now (e.g., NE North America, W Europe, some parts of S and SE Asia, see Mueller et al., 2012), yields
may decline in the future due to climate change (e.g., Elliott et al., 2013; Funk and Brown, 2009; Lobell
et al., 2009; Moore and Lobell, 2015; Pugh et al., 2016), and unless this can be counteracted by
520 different management (e.g., increased irrigation) or different crop varieties, production may need to

shift to other regions. However, the degree of climate change over our simulation period is too small to discern negative impacts on yields, and associated climate-driven crop area changes.

525 Aside of biophysical considerations, LULC changes in response to changing economic conditions as projected in the scenarios require support by adequate regional policy, production and trading systems as well as appropriate technological capabilities (e.g., Lambin et al., 2003; Meyfroidt et al., 2019). Weak governance structures, for instance, would allow highly market-driven LULC changes, especially arising from changing demand elsewhere. LUM projections involving large-scale separation of LULC types across global regions (i.e. large regions of just one LULC class, e.g., IMAGE_Base/BECCS, all MAgPIE scenarios, LUH1_60Stab, LUH2_SSP5-85) could be interpreted to be detrimental to regional to national food production systems. This would include, for instance, subsistence farming systems over wide parts of Africa, which are an essential pillar of Africa's food supply and will continue to be such in the future (e.g., Sulser et al., 2015). In addition, technological capacities would have to be in place to support crop production at the projected locations possibly including irrigation, the use of appropriate machinery, fertilization, etc. (see, e.g., Barrett and Toman, 2010; Lambin et al., 2014; Nilsson and Persson, 2012; Wang et al., 2016). At present, no global LUM is set-up to consider governance aspects, such as land tenure rights or location-specific management, or transportation and trade capacities (apart from assumptions made in the economic core of LUMs that apply to large regions), which is an important need for further development. To better understand regional LULC allocations and the related impacts on ecosystems and ecosystem services, the availability of more spatial information from LUMs related to regional-scale assumptions on technological progress, flows of food import, export and local production would be useful.

540 **(4) Impacts on ecosystems and ES indicators.** The LULC patterns observed in the 16 scenarios suggested a general prioritization of food and feed demand affecting croplands and pastures (production of crops, meat, etc.) over those related to natural land dynamics (e.g., C storage, biodiversity). This is not surprising, given that aspects that could impact "non-food" demands, such as carbon prices are not considered in many of the scenarios' underlying storylines. In LUMs where both, a baseline scenario and scenarios with additional demands, were simulated (CLUMondo, IMAGE, MAgPIE), the overall trends in LULC and ES indicator changes were chiefly determined by the demands of the baseline scenario and their model-specific implementation. Specific additional demands, e.g. for land-based mitigation or conservation, mostly resulted in only small deviations of LULC patterns and ES changes from the baseline scenario. Deviations between scenarios of different models were much larger.

555 Scenarios that included specific climate change mitigation targets (CLUMondo_CStor, IMAGE_ADAFF/BECCS, MAgPIE_ADAFF/BECCS) resulted in larger total C storage in LPJ-GUESS, but lower crop production, compared to the baseline scenarios. In LUMs, the mitigation scenarios appear to include technological-driven yield increases, which are higher than those assumed in LPJ-GUESS (see methods). From a C storage perspective, concern about the C storage potential calculated by LUMs was raised by Krause et al. (2018), who could not reproduce the cumulative C uptake that was calculated in IMAGE and MAgPIE BECCS and ADAFF when applying their LULC change to ecosystem models. On average only 62% of C uptake was achieved with LPJ-GUESS, and about 55%, when three other DGVMs were used in addition. Likewise, Harper et al. (2018) also found the IMAGE C storage potential from BECCS to be achieved by less than 25% upon simulating two IMAGE mitigation scenarios with the JULES DGVM. These discrepancies likely arise from different assumptions in LUMs and DGVMs related to growth rates and C uptake of re-growing forests and bioenergy crops, changes in soil C stocks upon LULC change, legacy effects of previous land use and some further processes such as disturbances, e.g., forest fires. By contrast, when using the CLUMondo LULC patterns, all three scenarios led to an increase in total C storage in LPJ-GUESS, thus even exceeding the no-net carbon loss target that was implemented in CLUMondo_CStor. This might be explained by the joint effects of

570 N deposition, CO₂ fertilization and climatic change that are core components of the LPJ-GUESS model but which were not implemented in similar detail in the CLUMondo calculations.

575 A number of studies have begun to identify in more detail how different assumptions in LUMs might affect LULC projections. Stehfest et al. (2019) recently provided a comprehensive sensitivity analysis of the socio-economic drivers that were projected across five SSP-based storylines by six agro-economic models/IAMs and found very diverging sensitivities across models. The study highlights the existing variability in LULC modelling and emphasizes the need for more empirical research on crucial factors in the LULC modelling process such as long-term drivers of LULC change or the representation of land-use regulation and trade. The spread between LULC projections of different models could also be reduced by joint calibration and validation standards, but these are currently not existing (e.g., van Vliet et al., 2016). Reducing the spread between models, especially for similar scenario assumptions, would provide an important step forward in understanding LUMs LULC patterns and in identifying possible implausible allocations and would also support the assessment of calculated impacts on ecosystem functioning and ES. A comprehensive comparison of the socio-economic drivers of LUMs with the ES indicator levels simulated with DGVMs based on the LULC patterns from LUMs would be needed. This would provide deeper insights on the dependencies between drivers, modeling strategies and resulting ES provisions and would contribute to identifying the quality of the representation of interactions between socio-economic and environmental systems including relevant feedback mechanisms.

4.2. Variability in the future of global ES indicators

590 Despite the partially very diverging LULC projections, the 16 land use scenarios on the level of global totals (see Fig. 3, Table S3) resulted in a positive change in NPP, vegetation C (all except one scenario), crop production and annual water runoff, and in a negative change of soil and litter C stocks (all except one scenario) from 2000-2004 until 2036-2040 when simulated with LPJ-GUESS. Diverging trends were predicted for evapotranspiration. The agreement, first of all, shows that the absolute impacts on ecosystem functionality from joint climate change and increasing atmospheric CO₂ levels even under RCP 2.6 exceeded impacts of LULC changes, although we didn't quantify relative climate and CO₂ impacts separately. A sensitivity test using climate inputs from five GCMs, instead of just one, along with the four diverse scenarios from the LUH1 product in our simulation set-up showed additional uncertainties between 0.1% and 8.6% for the ES indicators considered here (Table S6). The lowest deviation due to different GCM implementations was found for crop production and the highest for vegetation C stocks.

Regionally, large variability in ES indicators (see right maps in Fig. 4 and Fig. S2) reflected the diverging LULC scenarios (effects from scenario storylines and model-specific implementation) and their interactions with climatic changes. Only in areas colored white, the absence of variability in changes of ES indicators indicate dominating climate change and CO₂ impacts. Variability in the predicted changes of global totals in ES indicators exceeded a low level of 1-2% for vegetation C stocks ($\pm 4.1\%$) and crop production ($\pm 12.2\%$) with regional variabilities (standard deviation of relative changes across scenarios) being high for these two indicators in nearly any productive region (Fig. 4). We discuss the observed regional variability in ES indicators on the level of biomes as large regions with similar ecological constraints (see Fig. S4 for biome classification).

610 Tropical forest regions, or at least major regions therein, were identified as hotspots of variability across the LULC projections with large areas showing variability >10% change across the scenarios for all ES indicators considered in this study (see Fig. 4, Fig. S2 and Table S7 for biome averages of ES

615 indicators). This is a result from the high vegetation productivity, large biomass and a relatively higher
CO₂ fertilization on the one hand and very diverging trends in the LULC changes across the 16 scenarios,
especially at the borders of the currently forested tropics (see also Prestele et al., 2016), on the other
hand. For instance, losses of soil and litter C stocks are the net effect of higher decomposition rates as
a consequence of a warmer climate in combination with higher inputs under CO₂-driven increased
productivity. These climatic effects are strongly reinforced by the conversion of forests to croplands
620 (LUH1_26Be) and pastures (all IMAGE scenarios, LUH2_SSP3-70, LUH2_SSP5-85, to some degree also
CLUMondo scenarios) leading to even lower soil and litter C stocks. At the same time they would be
attenuated through forest regrowth (LUH1_45Aff, LUH1_60Stab, MAgPIE_ADAFF), reducing regional
carbon losses or even resulting in gains in soil and litter C stocks. As is well documented, future
increased use and fragmentation of tropical forest ecosystems can be a major threat to conserving
625 tropical ecosystems and biodiversity (e.g., DeFries et al., 2005; Lewis et al., 2015; Taubert et al., 2018)
and the existing protected area network is insufficient to provide the necessary protection (Laurance
et al., 2012). Developing joint biodiversity and carbon storage policies might lead to possible
reinforcing synergies (e.g., Strassburg et al., 2019), although appropriate governance schemes to
support such attempts would still be a crucial factor.

630 In tropical savannas and temperate shrubland and grassland regions, the diverging LULC projections
resulted in high variabilities for vegetation productivity, vegetation C storage, annual water runoff and
crop production. Although 15 out of 16 land-use scenarios increase cropland area in these regions,
they diverged widely in the exact location of cropland expansion resulting in these high variabilities in
ES. Savannas have been highlighted before as particularly vulnerable to future conversions of natural
635 vegetation into cropland or pasture (e.g., Shin et al., 2019) because of large population growth in many
savanna regions, their climatic suitability for agriculture and relatively small efforts needed for
conversion considering the relatively low woody vegetation cover. Parts of these regions experienced
intense cropland expansion already in recent decades, such as Brazils Cerrado and Chaco or African
savannas (e.g., Aleman et al., 2016; Hansen et al., 2013; Noojipady et al., 2017). Processes affecting
640 ecosystem functionality and services in these subtropical to semi-arid regions are particularly
important also in view of rapid population growth and associated demands (Alexandratos and
Bruinsma, 2012) and also their role in global C cycle and climate dynamics (e.g., dominant role for the
trend and interannual variability of the global land carbon sink, see Ahlström et al., 2015, with their
semi-arid class widely corresponding to our classes tropical savannas and temperate shrublands and
645 grasslands). Therefore, high variability in the provision of ES indicators related to vegetation
productivity, water availability and food supply may have severe consequences on ecological,
economic and social systems in these regions.

In both temperate and boreal forest regions, the regional variability of vegetation productivity and
vegetation C storage was high because the increased photosynthetic productivity and longer growing
650 seasons under warmer climates in higher latitudes were either dampened or amplified by diverging
LULC projections. While LULC changes dominate this combined positive effect in temperate regions,
they are much smaller in boreal regions and the climatic effect dominates (see Table S5, compare also
high variability of changes in NPP, vegetation and soil/litter C in boreal regions for multiple DGVMs,
GMCs and emission pathways in Nishina et al., 2015, under fixed LULC). Counteracting these positive
655 trends, studies highlight new challenges for temperate and boreal forests emerging from climatic
changes and anthropogenic disturbance with the capacity for severe ecosystem-level damages, such
as droughts, insects, fire regimes and pathogens (e.g., de Groot et al., 2012; Millar and Stephenson,
2015; Park et al., 2014). Because these processes are only to some degree implemented in LPJ-GUESS

660 (see, e.g., Pugh et al., 2019), this could further increase the regional variability in ES indicators as
indicated in this study. Regional variability was high also for crop production due to diverging
extensification and intensification trends across temperate and boreal regions. Land-use changes and
associated regional variability in ES indicators in the cold (tundra) and warm desert regions are not
significant in a global context because of the climatically constrained low productivity, although it is
enhanced at least in tundra regions through warmer temperatures.

665

4.3. Significance of our approach

The IPBES report on plausible futures of nature identified some general trends across their scenarios
(e.g., continued increase in managed land, increases in material and decreases in regulating and non-
material nature's contributions to people) and rated the knowledge base and confidence in effects of
670 interactions of future LULC and climatic changes on biodiversity and ecosystem functioning with
"established but incomplete" (see Shin et al., 2019). By evaluating 16 scenarios of five structurally
different LUMs, we covered a large variability existing in currently available spatially-explicit
projections of LULC and therefore contributed to extending the existing knowledge base on variability
of future ES indicators. However, conclusions drawn here in regard to projected changes in LULC and
675 ES indicators are inherently dependent on the selected set of LUMs and scenarios, evaluation time
period and simulation set-up. In addition, we did not consider climatic variability resulting from
different GCM implementations of climate under RCP 2.6 nor other possible emission pathways, which
both adds uncertainty to future ES indicator levels. Previous studies (e.g., Friend et al., 2014; Krause et
al., 2019; Nishina et al., 2015; Pugh et al., 2018) explored the variability of using different ecosystem
680 models with the same or multiple LULC and climate pathways, while Ahlström et al. (2012) and
Schaphoff et al. (2006) used climate forcing data from multiple GCMs following the same emission
pathway instead of only one climate model to quantify ES indicators. Our sensitivity test using climate
inputs from five GCMs and the four LUH1 scenarios indicated uncertainties between 0.1% and 8.6%
for the ES indicators considered here (Table S6). The fact that crop type distribution and N fertilization
685 was taken directly from the LUMs for IMAGE and MAGPIE simulations was considered as an extension
of the LULC input from the LUMs and therefore as a part of the LULC scenarios of these models. In this
study we considered the near to medium future until 2040. Estimates of ES indicator levels and their
variability for the far future until 2100 are likely different.

690 5. Conclusions

We conclude that LUMs and IAMs have fundamental limitations in capturing all relevant processes
related to LULC changes. In some scenarios this results in questionable and potentially unrealistic
features in their regional LULC allocations and their global and regional trends. More spatial
information from LUMs related to regional assumptions (e.g., on technological progress, flows of food
695 import, export and local production) in addition to LULC patterns would be helpful to better
understand their regional LULC allocations. Limitations also include technical aspects of LUMs such as,
for instance, adequate spatial resolution, representation of net vs. gross LULC changes, number of
LULC classes. We can only deduce a generally high influence of model-specific singularities from our
findings, although we couldn't attribute the discrepancy in LULC patterns to the individual factors in
700 the LULC modelling process based on the available LUM data.

705 The variability across the 16 LULC scenarios entails a high variability in the trends of most ES indicators investigated in this study. On a regional level, this emphasizes the role of tropical forests, and especially the borders of the currently forested tropics, as regions with most uncertain future developments that have the potential to significantly alter regional ecosystem functionality and services in a way that is significant in a global context. Among the investigated ES indicators, the identification of crop production as the indicator that was associated with the by far highest uncertainties in terms of global totals and regional variabilities, highlights diverging production targets but also different regional strategies of the investigated models to fulfill future demands for crop production.

710 Our results stress that information from individual LUMs or IAMs, that is used for policy support towards sustainable transformations, should be complemented by further information such as the variability of ES indicators arising through different LULC projections. This would provide a wider context that is essential to be acknowledged in policy making. For regional decision making, this is especially important in regions with highly diverging trends in land-use scenarios and therefore large variability in ES indicators. The issue may become even more relevant in the second half of the century, when LULC changes for climate change mitigation and adaptation are likely to intensify. Ultimately, we need to find improved ways to achieve a better integration between models targeting the different aspects in the cycle of socio-economic developments and their direct, indirect and cumulative implications on natural systems.

720 **Author contribution**

A. D. Bayer and A. Arneth conceived and designed the experiments. P. H. Verburg and R. Fuchs made CLUMondo data available and converted them for this study. P. Anthoni prepared LUH2 input data for LPJ-GUESS and assisted in the LPJ-GUESS model simulations. R. Mey, A. Krause and A. D. Bayer carried out the model simulations and led the data analysis with contributions from all authors. R. Fuchs contributed with the analysis of spatial-temporal patterns of land-use models. A. D. Bayer led the writing of the manuscript with contributions from all authors.

Acknowledgements

730 This work was funded by the European Commission's 7th Framework Program under Grant Agreement numbers 308393 (OPERAs) and 603542 (LUC4C). This work was supported through the Helmholtz Association and its research program ATMO. The authors thank the research groups for making climate model data (ISI-MIP) and land-use model data available to the community. We thank K. Winkler for providing numbers on historical LULC changes.

Table 1. Overview of land-use models and scenarios used in this study. Main references are given for each model and the scenarios applied in this study. See also references therein for further details.

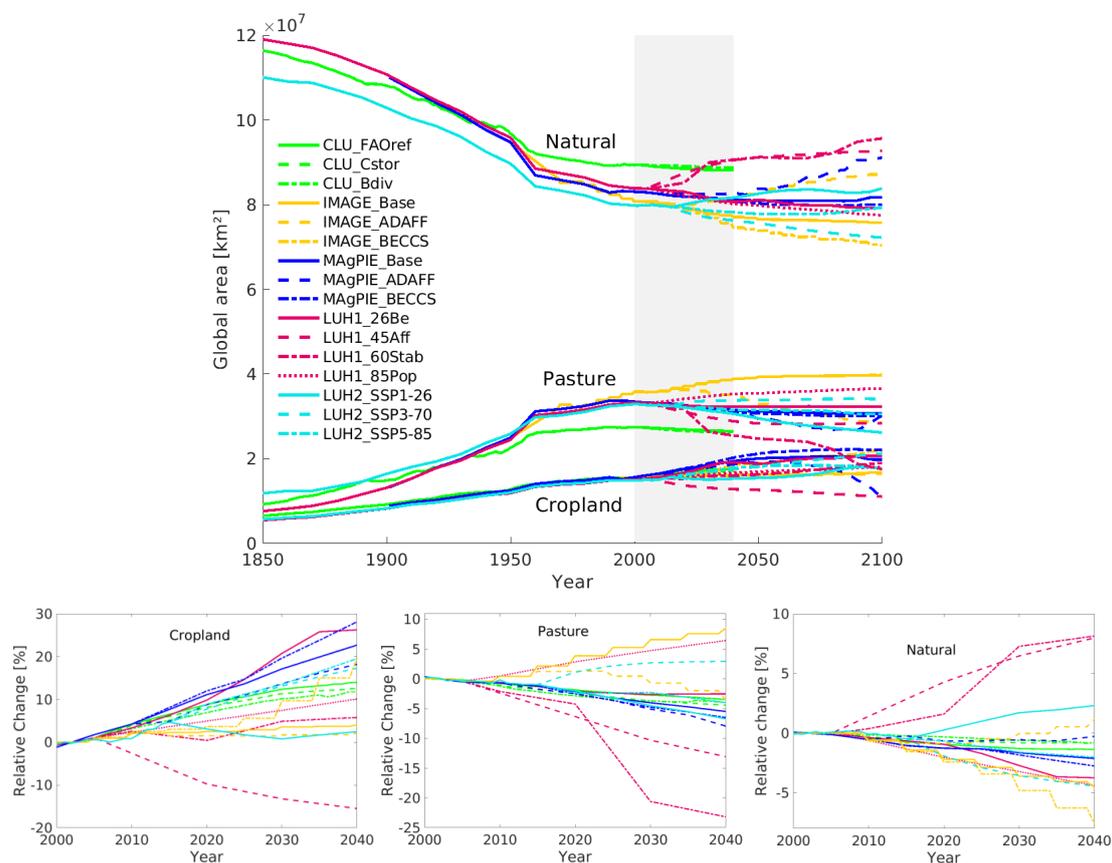

Land-use model	Technical characteristics ¹	LU categories and additional information	Allocation procedure	Consideration of climate change
CLUMondo (van Asselen and Verburg, 2013; Eitelberg et al., 2016)	S: 9.25 km x 9.25 km, Eckert IV projection, T: future 2001-2040, annual, B: starts from land use in 2000 after (Ramankutty et al., 2008) (Asselen and Verburg, 2012).	24 land systems types as combinations of extensive/medium intensive/intensive cropland, mosaic cropland and grassland, dense/open forest, bare land and built-up area (Note: pigs/poultry are excluded as a defining characteristic).	Spatially explicit allocation of land systems to fulfill the demand of 24 world regions. As long as demands are not satisfied, land systems that contribute more to a standing demand are preferred. No trade between world regions assumed.	None. Present climate and atmospheric CO ₂ level assumed.
IMAGE (Popp et al., 2017; Stehfest et al., 2014)	S: 26 world regions (for socio-economic parameters), 0.5°x0.5° (most environmental parameters, incl. land use) T: historic 1970-2005, future 2005-2100, annual, Bt: LU harmonized to HYDE 3.1 (Klein Goldewijk et al., 2011) in 2005 ¹ .	Fractional data for cropland, pasture, forest, urban, other natural.	Allocation relies on regression-based suitability assessment and iterative allocation procedure until demands are met.	Yes. All scenarios base on RCP2.6 climate from IPSLCM5A-IR general circulation model bias corrected to the 1960–1999 historical period. Varying CO ₂ level with 490 ppm in 2100.
MAGPIE (Lotze-Campen et al., 2008; Popp et al., 2014, 2017)	S: 10 world regions, (0.5° x 0.5° resolution, clustered to 500 units based on similarity in the modeling, see Humpenöder et al., 2014), T: future 1995-2100, 5 year steps, B: LU harmonized to HYDE 3.1 (Klein Goldewijk et al., 2011) in 1995.	Fractional data for cropland (irrigated, non-irrigated), pasture, forest, urban, other natural.	Achieve demands under minimizing costs in 10 world regions with recursive dynamic optimization. Cost minimization defines land availability. International trade considered (Humpenöder et al., 2014).	Yes. All scenarios base on RCP2.6 climate impacts same as IMAGE.
LUH1 (Hurt et al., 2011)	S: 0.5°x0.5° WGS84, T: historic 1500-2005, future 2005-2100, annual, B: historic product is based on (Klein Goldewijk et al., 2011).	Fractional data for cropland, pasture, primary vegetation, secondary vegetation Gross transitions between land-use classes based on shifting cultivation in some tropical regions.	Allocation for historic period based on HYDE 3.1 (land-use/capita using weighting maps for built-up area, population density, soil suitability, coastal areas/river plains, annual mean temperature). Additionally, LUH1 uses the following features to process land use change: -Shifting cultivation rates -Deforestation for agricultural land included in wood harvest statistics -Priority for land conversion (agricultural land taken from primary or secondary) For the future, the allocation is dependent on the four IAMs used for the scenarios (at 2° x 2° resolution), disaggregated to 0.5° x 0.5°.	Yes. Consideration of different Representative Concentration Pathways (RCPs) from the different IAMs.
LUH2 (Hurt et al., 2020, data from http://luh.umd.edu)	S: 0.25°x0.25° WGS84, T: historic 850-2015, future 2016-2100, annual, B: 850–2015 land-use based on HYDE 3.2 (Goldewijk et al., 2017).	Fractions for cropland (C3/C4 annuals, C3/C4 perennial, C3 nitrogen fixing), managed pasture, rangeland, primary land, secondary land, urban.	Allocation for historic period based on HYDE 3.2 and globally available statistics and for the future period based on transitions and additional information from IAMs (see also their respective allocation procedures, compare references in (Hurt et al., 2020). Additionally, LUH2 uses the following features to process land use change: - crop type and rotations - Shifting cultivation rates - Historical wood harvest statistics and future forest transitions - Biomass density and recovery rates - Priority for land conversion.	Yes. Consideration of different RCPs from the different IAMs.

Scenarios
<ul style="list-style-type: none"> FAOref: demands of tons of crop production, size of livestock and population (as built-up area) as expected by FAO until 2040. Demands projected to 24 world regions by the integrated assessment model IMAGE. Cstor: In addition to FAOref extra demand for C storage implemented with a no-carbon-loss approach. This results in the favorable consideration of land systems with high C storage capacity such as dense forests in the allocation procedure. Bdly: In addition to FAOref extra demand for protected areas. Protected areas used that follow national biodiversity targets according to Aichi target number 11. Forest and grassland proportions of natural, semi-natural and managed natural land systems were selected to account for protected areas in CLUMondo land systems dense forest, mosaic grassland and forest, mosaic grassland and bare, natural grassland. Favorable consideration of land systems with high amount of protected areas in allocation procedure. Land systems in land areas assigned to IUCN categories I to IV at the beginning of the simulation procedure were maintained throughout the scenario.
<ul style="list-style-type: none"> Base: land-use change driven by increased food demand and population growth according to SSP2. ADAFf: Demands as in Base scenario with additional CDR target of 130 GtC by 2100. Land-based mitigation achieved by avoided deforestation and afforestation. BECCS: Demands as in Base scenario with additional CDR target of 130 GtC by 2100. Land-based mitigation achieved by bioenergy plant cultivation and subsequent carbon capture and storage.
<ul style="list-style-type: none"> Base: land-use change driven by increased food demand and population growth according to SSP2. ADAFf: Demands as in Base scenario with additional CDR target of 130 GtC by 2100. Land-based mitigation achieved by avoided deforestation and afforestation. BECCS: Demands as in Base scenario with additional CDR target of 130 GtC by 2100. Land-based mitigation achieved by bioenergy plant cultivation and subsequent carbon capture and storage.
<ul style="list-style-type: none"> 268e: Scenario following RCP 2.6 where the cultivation of bioenergy crops with CCS sequestering carbon that significantly balances C so that global warming saturates below 2°C until 2100. Increased land demand for bioenergy crops, which occur near existing agricultural areas, natural areas are declining. Simulated by IMAGE IAM. 45Af: Scenario following RCP 4.5 assuming that global GHG emission prices support climate change mitigation by massive afforestation programs around the world with the aim to preserve large C stocks in forests. Vast expansion of forested areas slightly decreases the area of arable land, but assumed technological improvements and more efficient global trading systems keep up agricultural production to satisfy demands. Simulated by dynamic recursive economic model GCAM. 605tab: Scenario following RCP 6.0 assuming stabilization with a medium population growth throughout the 21st century and climate change mitigation efforts only become effective in the last third of the century. Intensification and expansion of cropland area cover the increased food demand. Simulated by AIM and other models. 85Pop: Scenario following RCP 8.5 assuming rapid population growth to 12 billion people in 2100 and a global temperature rise by more than 4 °C until 2100. Intensification is supported by technological improvements as the most important driving factor to satisfy a high food demand. Cropland expands as well as pasture especially in developing countries, while natural areas decline. Simulated by MESSAGE IAM.
<ul style="list-style-type: none"> SSP1-26: Scenario combining SSP 1 and RCP 2.6 of an environmentally friendly world with low population growth, high urbanization, relatively low demand for animal products and high agricultural productivity. Land use and land use change is relatively low and policies targeting the reduction of atmospheric greenhouse gases (including BECCS and afforestation) are implemented so that an additional forcing is limited to 2.6 W m⁻² by 2100. Simulated by IMAGE 3.0 IAM where LULC is allocated iteratively based on suitability assessment until demands are met. SSP3-70: Scenario combining SSP 3 and RCP 7.0 focused on regional development. High population growth in developing countries, slow economic development and per capita food consumption lead to high expansion of agricultural areas rather than agricultural land intensification under relatively high level of climate change with a radiative forcing of 7.0 W m⁻² by 2100. Simulated by AIM/GCE IAM framework working based on the adjustment of prices until supply and demand for commodities and services equilibrate. SSP5-85: Scenario combining SSP 5 and RCP 8.5 of a world characterized by strong economic growth that is based on fossil fuels, with low population growth, high urbanization, and high food demand per capita with high agricultural productivity due to technological progress. Strong expansion of global cropland and the level of climate change is high with an assumed radiative forcing of 8.5 W m⁻² by 2100. Simulated by REMIND/MAGPIE IAM framework where LULC changes are modelled chiefly based on prices and quantities of bioenergy and greenhouse gas emissions.

¹S: spatial resolution and projection, T: time horizons, B: underlying data bases or historical land-use baseline from which scenarios start,

²small deviations in the area of the land-cover classes between MAGPIE/IMAGE and HYDE 3.1 land-use in 1995/2005 occurring due to different land masks and calibration routines.

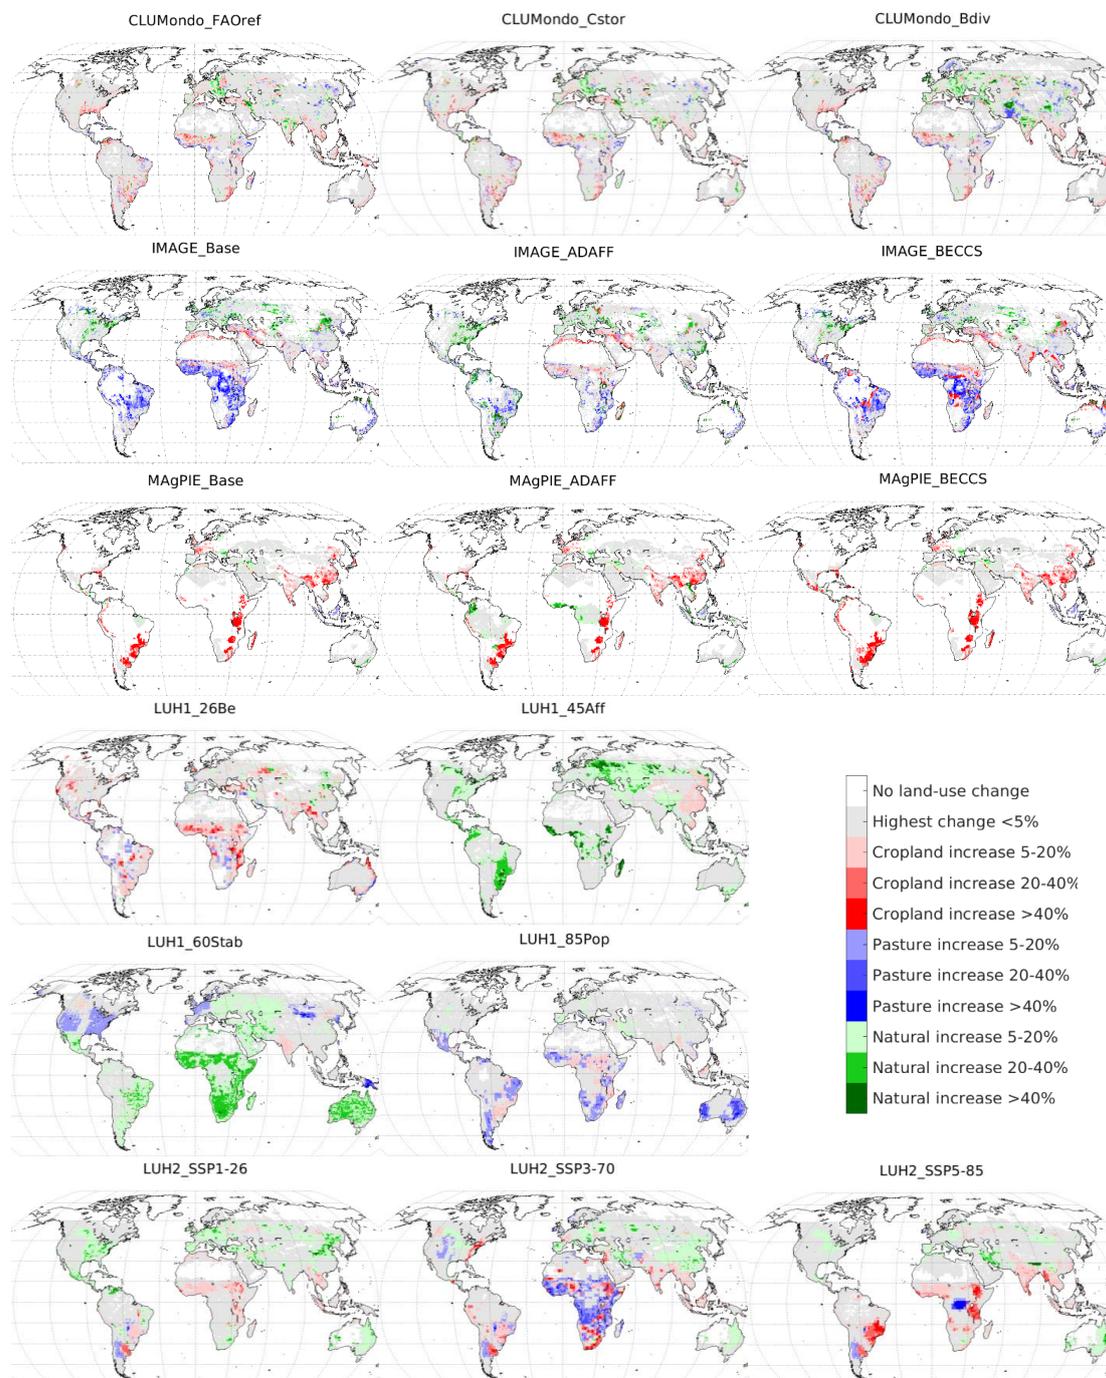

1140

Fig. 1. Absolute land area of croplands, pastures and natural areas between 1850 and 2100 for 16 scenarios of five land-use models and detailed relative changes in LU from 2000 to 2040 analyzed in this study.

1145

1150 Fig. 2. Categories of dominant land-use change from 2000-2004 to 2036-2040 for each of 16 land-use scenarios. The legend is identical for all plots.

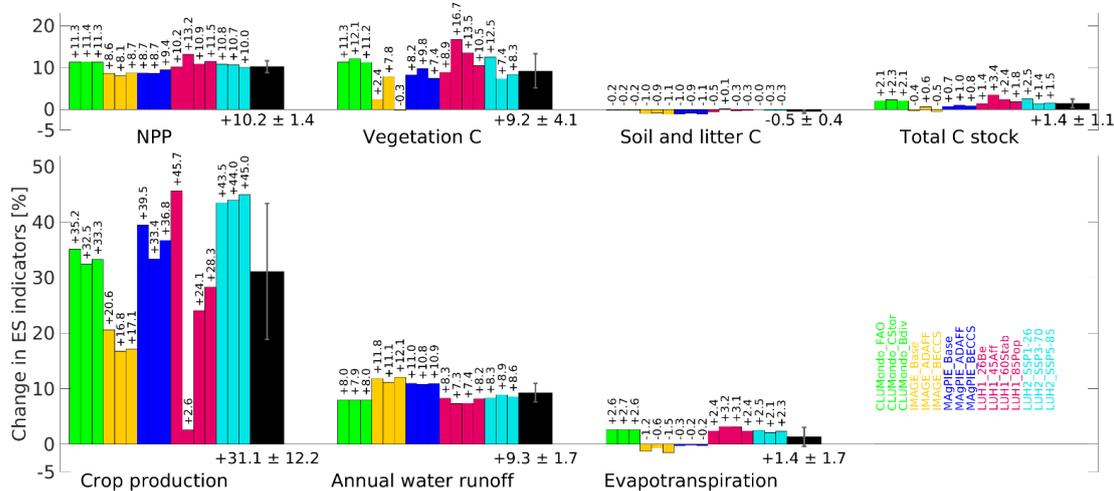

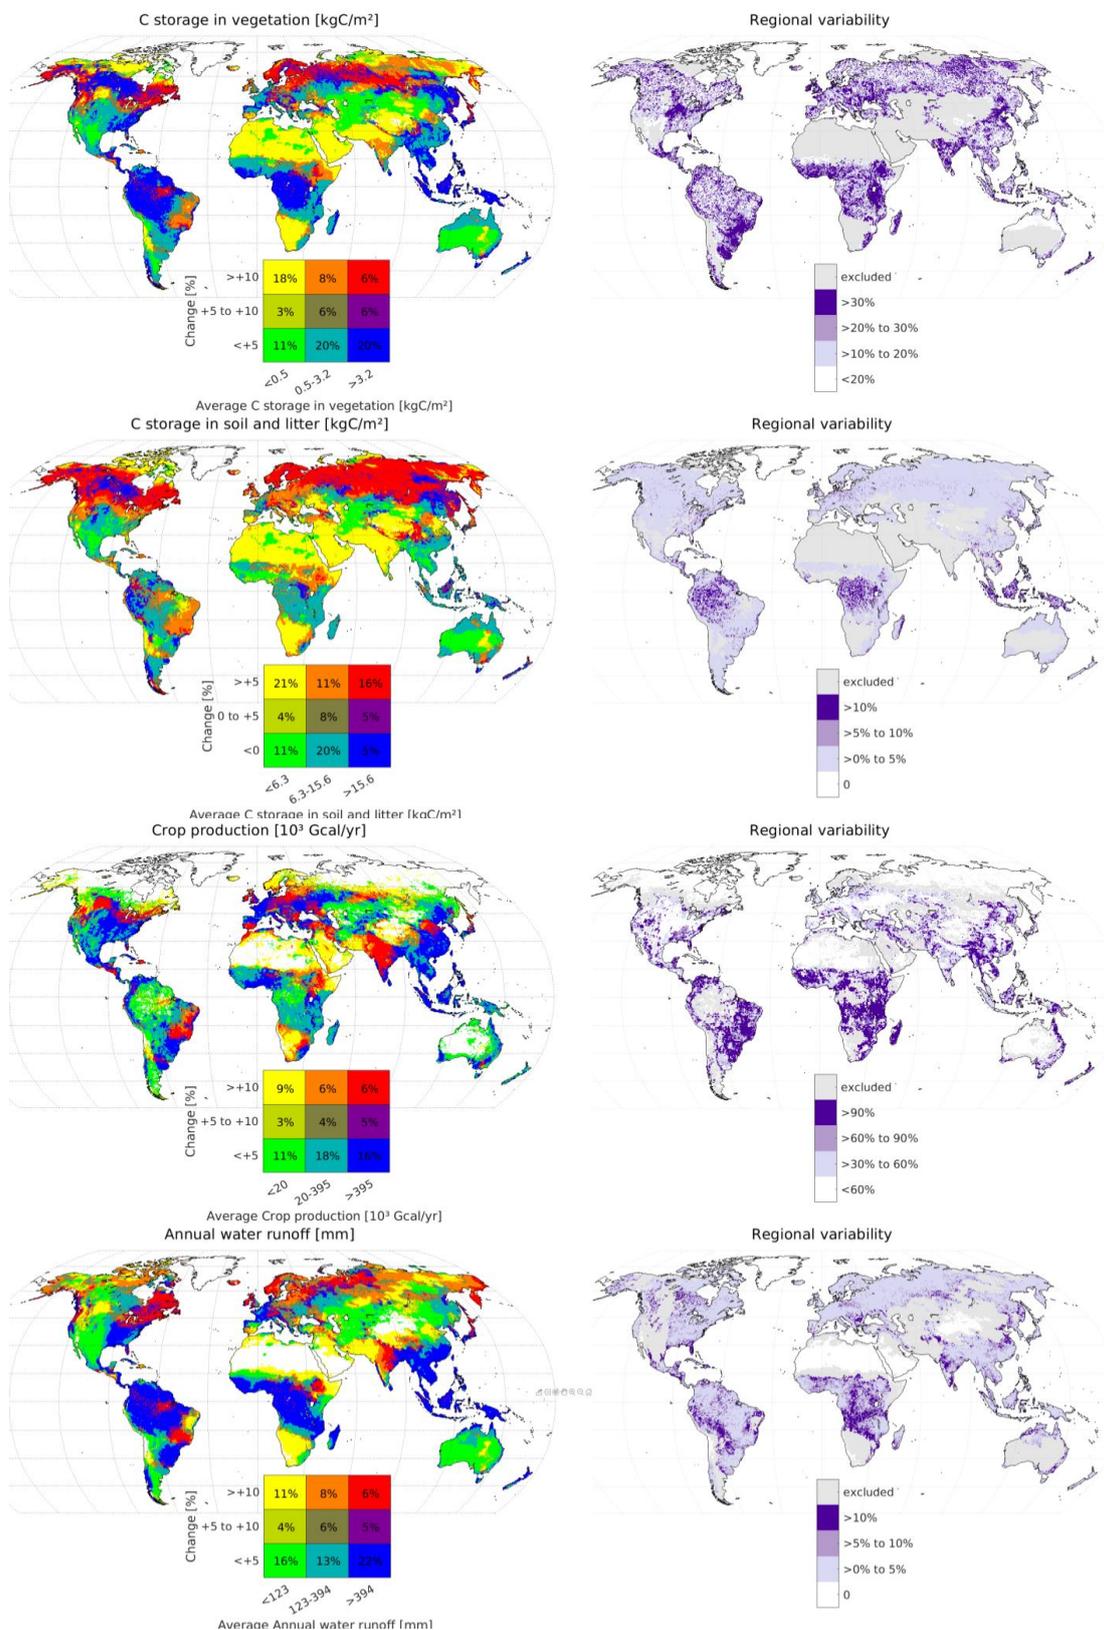

Fig. 3. Change and uncertainty in ES indicators from 2000-2004 to 2036-2040 relative to base level in 2000-2004 across 16 land-use scenarios in percent. Black bars give average and standard deviation of the relative changes across all scenarios. See Table S3 for absolute levels and changes for each scenario.

1155

1160 Fig. 4. Left maps show categories of the average level of the provision of selected ES indicators in 2000-2004 and
the relative change until 2036-2040 averaged over 16 land use scenarios. Thresholds for categories for the average
ES indicator level follow 33rd and 67th percentiles for each ES indicator while the change in indicators is given in 5%
1165 steps for all indicators to allow for comparability. Note that for soil and litter C the lowest category is negative. At
high levels of ES indicator provision (highest 33% of values), blue cells mark regions where on average little change
and red cells where high changes are expected until 2040. The yellow category marks regions where base levels in
ES provision are low. Therefore, relative changes in them can be very high but are of minor importance. The
percentage of global land area in each category is indicated in %. Cells where the average indicator level in 2000-
2004 is 0 are colored white and excluded from the statistics. Right maps give the variability of the percent change
1170 in each ES indicator for each cell which was calculated as the standard deviation of the changes in the ES indicator
from 2000-2004 to 2036-2040 that was derived for each of the 16 land use scenarios individually. Regions, where
the base level in 2000-2004 was below the 33rd percentile (yellow to green cells in left maps) were excluded in
regional variability maps and colored grey to focus on cells with relevant ES indicator provision. Note that the legend
scaling is different for vegetation C and crop yield production. Purple regions indicate a standard deviation in the
1175 predicted relative changes of this indicator higher than 10% of the indicator level in 2000-2004 (30% for vegetation
C, respectively, 90% for crop yield production). See SI Fig. S2 for NPP, total C storage and evapotranspiration.
