Abstract. The stability of the Greenland Ice Sheet under global warming is governed by a number of dynamic processes and interacting feedback mechanisms in the ice sheet, atmosphere and solid Earth. Here we study the long-term effects due to the interplay of the competing melt-elevation and glacial isostatic adjustment (GIA) feedbacks for different temperature step forcing experiments with a coupled ice-sheet and solid-Earth model. Our model results show that for warming levels above 5 2°C, Greenland could become essentially ice-free on the long-term, mainly as a result of surface melting and acceleration of ice flow. These ice losses can be mitigated, however, in some cases with strong GIA feedback even promoting the partial recovery of the Greenland ice volume. We further explore the full-factorial parameter space determining the relative strengths of the two feedbacks: Our findings suggest distinct dynamic regimes of the Greenland Ice Sheets on the route to destabilization under global warming – from recovery, via quasi-periodic oscillations in ice volume to ice-sheet collapse. In the recovery 10 regime, the initial ice loss due to warming is essentially reversed within 50,000 years and the ice volume stabilizes at 61-93% of the present-day volume. For certain combinations of temperature increase, atmospheric lapse rate and mantle viscosity, the interaction of the GIA feedback and the melt-elevation feedback leads to self-sustained, long-term oscillations in ice-sheet volume with oscillation periods of tens to hundreds of thousands of years and oscillation amplitudes between 15-70% of present-day ice volume. This oscillatory regime reveals a possible mode of internal climatic variability in the Earth system on 15 time scales on the order of 100,000 years that may be excited by or synchronized with orbital forcing or interact with glacial cycles and other slow modes of variability. Our findings are not meant as scenario-based near-term projections of ice losses but rather providing insight into of the feedback loops governing the "deep future" and, thus, long-term resilience of the Greenland Ice Sheet.

1 Introduction

The Greenland Ice Sheet (GrIS) holds enough water to raise global sea levels by more than 7.4 m and is continuously losing mass at present, thereby contributing to global sea-level rise (Morlighem et al., 2017; Frederikse et al., 2020). Current mass loss rates of 286 Gt/yr are observed, a 6-fold increase since the 1980's (Mouginot et al., 2019). Here, approximately 35 %
5 can be attributed to a decrease in climatic mass balance and 65 % are due to an increase in ice discharge. While it has been suggested that the Greenland Ice Sheet could become unstable beyond temperature anomalies of 1.6 – 3.2 °C due to the self-amplifying melt-elevation feedback (Levermann and Winkelmann, 2016), recent studies debate whether a tipping point might have already been crossed (Robinson et al., 2012; Winkelmann et al., 2011; Boers and Rypdal, 2021). Understanding the feedback mechanisms and involved time scales at play in GrIS mass loss dynamics is necessary to understanding its stability
10 under climatic changes.

Changing climatic conditions during the glacial cycles had a strong influence on the ice volume of the Greenland Ice Sheet. It varied from 3-7 m sea-level equivalent (that is the volume above floatation, divided by the total ocean area) in the last interglacial (from 126 to 115 kyrs BP) to 12 m during the last glacial maximum (19-20 kyrs BP) (Vasskog et al., 2015), while the present day volume of the GrIS is 7.42 m. Various processes and feedbacks in the ice sheet, atmosphere, ocean and solid Earth
15 governing the ice dynamics, like ice-ocean interactions, the melt-elevation feedback, and the snow-albedo feedback played an important role in past transitions from interglacial to glacial and vice versa (Denton et al., 2010; Willeit and Ganopolski, 2018; Pico et al., 2018). In this way, the GrIS has been a key component in the emergence of glacial cycles and their implications for overall Earth system stability, as can also be analyzed from a dynamical systems point of view (Crucifix, 2012). Simple models also allow to study the "deep future", i.e. the future on time scales beyond the ethical time horizon as defined e.g. by Lenton
20 et al. (2019), of the Greenland Ice Sheet and the Earth system and reveal that anthropogenic CO₂ emissions affect the climate evolution for up to 500 kyrs and can postpone the next glaciation (Talentó and Ganopolski, 2021).

One particular feedback, which, to our knowledge, has not yet been systematically studied in the context of the Greenland Ice Sheet, is the negative feedback in the interaction between the ice sheet and solid Earth (Pico et al., 2018). Here we aim to close this research gap, by systematically exploring how the feedback between solid Earth, ice, and climatic mass balance and
25 their interactions affect the long term response of the Greenland Ice Sheet.

Changes in ice load lead to glacial isostatic adjustment (GIA), a decrease in ice load initiates an uplift with characteristic time scales of hundreds to thousand of years (Barletta et al., 2018; Whitehouse et al., 2019). Currently observed post-glacial uplift rates in Greenland range between -5.6 mm/yr and 18 mm/yr (Adhikari et al., 2021; Wahr et al., 2001; Dietrich et al., 2005; Schumacher et al., 2018; Khan et al., 2008). Some studies suggest that uplift rates are higher in the South East, where
30 the Iceland hot spot has possibly passed, which can be associated with locally low viscosities in the upper mantle (Khan et al., 2016).

The viscous bedrock response is generally assumed to be slow compared to ice losses, with characteristic response time scales of tens to hundreds of millennia. However, several studies suggest that the viscosity of the asthenosphere and the upper mantle varies spatially and could be locally lower than previously thought (e.g. in Iceland, Patagonia, the Antarctic peninsula,

Alaska). This implies that the time scale of the viscous response to changes in ice load might be much shorter, e.g. close to tens or hundreds of years (Whitehouse et al., 2019). The elastic response component responds on an even faster time scale to changes in ice load, e.g. the 2012 extreme melt event caused a significant peak in GPS measured uplift rates (Adhikari et al., 2017). A model of the solid Earth can help to interpret the GPS measurements in order to distinguish the elastic uplift caused by recent mass losses from the delayed viscous uplift caused by the retreat of ice since the last glacial maximum, and deduce solid earth parameters like mantle viscosity and lithosphere thickness (Adhikari et al., 2021; Schumacher et al., 2018).

Efforts to model the solid earth response to changes in ice load range from local one-dimensional representations of the bedrock uplift to full three-dimensional models. The ELRA-type of model represents the solid earth as an Elastic Lithosphere and a Relaxing Asthenosphere by assigning a single time constant to the uplift response (Le Meur and Huybrechts, 1996; Zweck and Huybrechts, 2005). These models are computationally efficient and are often coupled to ice-sheet models in long-term simulations (Robinson et al., 2012). The Lingle-Clark model expands the elastic plate lithosphere with a viscous half-space and solves the equations explicitly in time (Lingle and Clark, 1985; Bueler et al., 2007). The relaxation time of the solid earth then depends on the spatial wavelength of the perturbation in ice load. However, this model uses only one constant value for the mantle viscosity, it does not include vertical or horizontal variations, nor does it solve the sea-level equation including self-consistent water-load changes or the rotational state of the Earth (Farrell and Clark, 1976; Hagedoorn et al., 2007) Such a model can be expanded to include more layers, e.g. the lower mantle, however, it becomes more difficult to constrain (Lau et al., 2016). One-dimensional solid earth models explicitly consider the spherical shape of the Earth instead of assuming a half space (Tosi et al., 2005; Fleming and Lambeck, 2004; Simpson et al., 2009; Lambeck et al., 2014). However, they do not represent lateral variations in solid-Earth parameters. Three dimensional models, which resolve not only several layers of the vertical dimension, but include additional variability in the horizontal direction, are developed to account for the ongoing discovery of lateral variations in viscosity and lithosphere thickness (Khan et al., 2016; Whitehouse, 2018; Whitehouse et al., 2006, 2019; Haeger et al., 2019; Martinec, 2000). A laterally varying 3D model can change the estimate of projected global mean sea-level rise due to an ice-sheet collapse in the West-Antarctic by up to 10% compared to a 1D model (Powell et al., 2021). Inferred values for mantle viscosities can span several orders of magnitude and therefore substantially impact the estimate of bedrock uplift rates as a response to present day ice losses (Powell et al., 2020). So far the coupling efforts between 3D solid-Earth models and physical ice-sheet models have been focused mostly on the Antarctic Ice Sheet, exploring the feedback between solid Earth and ice sheets and its potential to dampen or inhibit unstable ice sheet retreat (Gomez et al., 2013; De Boer et al., 2014; Gomez et al., 2018, 2020). Self-gravitation effects affect the stability of the grounding line (Whitehouse et al., 2019; Pollard et al., 2017) and GIA models which self-consistently solve the sea-level equation are crucial. Ongoing work focuses on the northern hemisphere, coupling for instance the Parallel Ice Sheet Model PISM to the solid-Earth model VILMA.

Similarly, modeling efforts of the climatic mass balance of the Greenland Ice Sheet range from computationally efficient temperature index models over energy balance models to sophisticated regional climate models, an overview can be found in the model intercomparison effort by Fettweis et al..

The response of the solid earth to ice loss can be part of a negative, meaning counteracting or dampening, feedback loop, called glacial isostatic adjustment (GIA) feedback, that can mitigate further ice loss. Studies focused on the GIA feedback

in context of the Antarctic Ice Sheet suggest that the bedrock uplift can lead to a grounding line advance and therefore has a stabilizing effect on glaciers that are subjected to the marine ice sheet instability (MISI) (Whitehouse et al., 2019; Konrad et al., 2015; Kingslake et al., 2018; Bassis et al., 2017; Barletta et al., 2018). However, to our knowledge the GIA feedback has not yet been addressed in the context of the Greenland Ice Sheet, where, in comparison to the Antarctic Ice Sheet, marine terminating
5 glaciers contribute less to mass loss. The feedback cycle we explore in this study is rather related to the self-amplifying melt-elevation feedback. The melt-elevation feedback establishes a connection between ice thickness and climatic mass balance: the lower the surface elevations the higher are typically temperatures and associated melt rates (see also Figure 1, in particular the orange arrows). An initial increase in melt thins the ice, bringing the ice surface to lower elevation. Subsequently the temperature increases and amplifies both, melt rates and ice velocities, and therefore leads to further ice loss and thinning. Once
10 a critical thickness is reached this feedback can lead to a destabilization of the ice sheet and irreversible ice loss (Levermann et al., 2013). (A similar feedback has also been known as the small ice cap instability (Weertman, 1961)).

This formulation of the melt-elevation feedback assumes a static bed, so that changes in ice thickness equal changes in ice surface altitude. GIA can mitigate this feedback: Due to bedrock deformation changes in ice thickness do not directly translate to changes in surface elevation. The loss of ice reduces the load on the bedrock and allows for a bedrock uplift, dampening the
15 melt-elevation feedback (see blue arrows in Figure 1). Due to the high viscosity of the mantle the glacial isostatic adjustment can manifest on a slower time scale than the climatic changes which cause the ice losses in the first place.

From a static point of view a compensation of 1/3 of ice thickness thinning due to GIA would be expected. In this study, we explore how the dynamic interaction of the feedbacks allows the GIA feedback not only to dampen but to (periodically) overcompensate for the melt-elevation feedback. Here we focus on the long-term stability of the Greenland Ice Sheet and how
20 it is affected by the positive melt-elevation feedback on the one hand and the negative GIA feedback on the other hand. We use simple representations of both, the melt-elevation and the GIA feedbacks, to study the interplay between them: The melt-elevation feedback is represented by an atmospheric temperature lapse rate which affects the melt rates. The GIA feedback is represented by the Lingle-Clark model, a generalization of the flat earth Elastic Lithosphere Relaxing Asthenosphere (ELRA) model (Bueler et al., 2007). The Lingle-Clark model accounts for non-local effects and different relaxation times depending on
25 the spatial extent of the perturbation. We explore the parametric uncertainty range by varying the key parameters: asthenosphere viscosity for the bedrock uplift and the atmospheric lapse-rate for the melt-elevation feedback.

We use the Parallel Ice Sheet Model (PISM) (the PISM authors, 2018; Bueler and Brown, 2009) coupled to the Lingle-Clark solid-Earth model (Bueler et al., 2007) in order to explore the interaction between the self-amplifying and the dampening feedback. The models and the experimental design are presented in Section 2. The warming experiments use an idealized
30 temperature forcing and are analyzed in Section 3, followed by a discussion in Section 4.

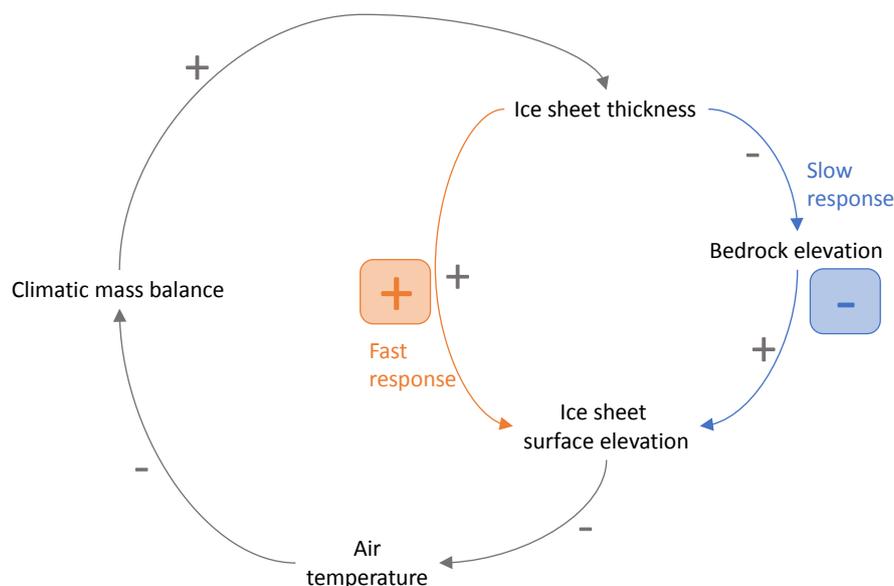

Figure 1. Interacting feedback loops for the proposed glacial isostatic adjustment feedback (GIA feedback). The orange part indicates the melt-elevation feedback: Higher air temperatures lead to decreasing climatic mass balance. This in turn leads to a decreasing ice thickness and in consequence to a decreasing ice surface elevation. If the surface elevation decreases, the air temperature rises due to the atmospheric lapse rate. This further decreases the climatic mass balance and leads to a positive (enhancing) feedback cycle. The timescale of this feedback cycle is driven by changes in the climate and is typically comparably fast. The blue part shows the counteracting mechanism of the ice load-bedrock uplift feedback. The decreasing ice thickness reduces the load on the bedrock, which leads to isostatic adjustment and therefore an uplift of the bedrock elevation. This mechanism partly counteracts the decrease in ice surface elevation and thus mitigates further increase in temperature. The timescale of this feedback loop depends on the rate of ice retreat and on the viscosity of the upper Earth mantle.

2 Methods

2.1 Numerical modeling

2.1.1 Ice-sheet dynamics with the Parallel Ice Sheet Model PISM

The Parallel Ice Sheet Model, PISM is a thermomechanically coupled finite difference ice-sheet model which combines the shallow-ice approximation (SIA) in regions of slow-flowing ice and the shallow-shelf approximation (SSA) of the Stokes flow stress balance in ice streams and ice shelves (Bueler and Brown, 2009; Winkelmann et al., 2011; the PISM authors, 2018). The internal deformation of ice is described by Glen's flow law, here the flow exponents $n_{SSA} = 3$ and $n_{SIA} = 3$ are used. We use the enhancement factors $E_{SSA} = 1$ and $E_{SIA} = 1.5$ for the SSA and the SIA stress balance respectively.

The sliding is described by a pseudo-plastic power law, relating the basal stress to the yield stress. The yield stress is determined from parameterized till material properties and the effective pressure of the saturated till via the Mohr-Coulomb criterion (Bueler and van Pelt, 2015).

2.1.2 Earth deformation model

5 While global GIA models with sea-level coupling are available, to our knowledge no coupling efforts between ice-dynamics and solid-Earth models have been undertaken for the Greenland Ice Sheet specifically. Here, the deformation of the bedrock in response to changing ice load is described with the Lingle-Clark (LC) model (Lingle and Clark, 1985; Bueler et al., 2007), incorporated as solid-earth module in PISM. In this model the response time of the bed topography depends on the wavelength of the load perturbation for a given asthenosphere viscosity (Bueler et al., 2007). The LC model uses two layers to model
10 the solid earth: the viscous mantle is approximated by a half space of viscosity ν and density ρ_r , complemented by an elastic layer of flexural rigidity D describing the lithosphere. The response of the elastic lithosphere happens instantaneously, while the response time of the viscous mantle lies between decades and tens of millennia, depending on both, the viscosity of the mantle and the wavelength of the change in load. While the Lingle-Clark model is not considering local changes to viscosity or lithosphere thickness (Milne et al., 2018; Mordret, 2018; Khan et al., 2016) and approximates the earth as a half space, the
15 relatively small spatial extent of the simulation region allows for such an approximation.

The resulting partial differential equation for vertical displacement u of the bedrock can be described by

$$2\nu|\nabla|\frac{\partial u}{\partial t} + \rho_r g u + D\nabla^4 u = \sigma_{zz}. \quad (1)$$

with g being the gravitational acceleration of the earth and σ_{zz} the ice load force per unit area (Bueler et al., 2007).

20 Here the flexural rigidity D is assumed to be 5×10^{24} Nm, assuming a thickness of 88 km for the elastic plate lithosphere (Bueler et al., 2007). The mantle density ρ_r is approximated with 3300 kg/m^3 .

2.1.3 Climatic mass balance and temperature forcing

The climatic mass balance in PISM is computed with the positive degree day (PDD) model from 2m-air temperature and precipitation given as inputs (Braithwaite, 1995). Here we use a yearly cycle of monthly averages from 1958 to 1967 of the outputs of the regional climate model RACMO v2.3 (Noël et al., 2019) in order to mimic preindustrial climate. The warming is
25 implemented as a spatially uniform instantaneous shift in temperature. The temperature forcing itself has a yearly cycle, with the temperature shift in winter being twice as high as in summer. This corresponds to an average Arctic amplification of 150 % (see also Robinson et al. (2012)).

The PDD method uses the spatially uniform standard deviation $\sigma = 4.23$, the melt factors for snow and for ice $m_i = 8 \text{ mmK}^{-1} \text{ day}^{-1}$, $m_s = 3 \text{ mmK}^{-1} \text{ day}^{-1}$ (PISM default) respectively. The melt-elevation feedback is approximated by an at-
30 mospheric temperature lapse rate Γ , so that local changes in the ice-sheet topography alter the temperature as

$$T_{ij} = T_{ij,\text{input}} - \Gamma \cdot \Delta h_{ij}, \quad (2)$$

with T_{ij} being the effective temperature at grid cell i, j feeding into the PDD model. $T_{ij, \text{input}}$ is the temperature at i, j given by the input, without any lapse rate correction, Γ is a spatially constant air-temperature lapse rate. $\Delta h_{i,j} = h_{t,ij} - h_{0,ij}$ is the local difference in surface elevation at i, j at time t , compared to a reference topography h_0 . Here we use the initial state for h_0 . The value of the lapse rate Γ , and thereby the strength of the melt-elevation feedback, is varied between 5 K/km and 7 K/km in the
5 experiments. The yearly precipitation cycle remains prescribed, the local temperature affects how much of the precipitation is perceived as snow and therefore adds to the accumulation: at a temperature above 2°C, all precipitation is perceived as rain, below 0°C all is perceived as snow, with a linear interpolation between the two states.

2.2 Experimental design

Here we use a spatial resolution in x and y direction of 15 km in order to do many simulations over 0.5 million years. The
10 spatial resolution in z-direction is quadratically decreasing from 36 m in the cell closest to the bedrock to 230 m in the top grid cell of the simulation box (at 4000 m above bedrock).

The temperature forcing is a spatially uniform step forcing, which is applied from $t = 0$ over the whole simulation time. Additional local temperature changes happen due to the atmospheric temperature lapse rate, as shown above. We explore different values for the atmospheric lapse rate in order to estimate the response of the system to changes in the strength of the
15 melt-elevation feedback.

The ice-ocean interaction is modeled via PICO, with ocean temperatures and salinities taken from the World Ocean Atlas version 2 (Zweng et al., 2018; Locarnini et al., 2019). Temperatures and salinities are averaged at bottom depth over the extended drainage sectors of the GrIS. For the extended sectors, the drainage sectors of Rignot and Mouginot (2012) are extended linearly into the ocean. The warming signal at depth generally stabilizes at lower levels than the atmospheric or
20 sea surface warming, here we assume that only 70% of atmospheric warming reaches the ocean ground (see also Albrecht et al. (2020)). Calving is modeled as a combination of eigencalving (Winkelmann et al., 2011; Levermann et al., 2012) and von-Mises calving (Morlighem et al., 2016) with constant calving parameters.

2.2.1 Initial state

The initial state is in equilibrium for constant climate conditions. The misfits of the initial state compared to observed velocities
25 (Joughin et al., 2018) and thicknesses (Morlighem et al., 2017) and to modelled climatic mass balance (Noël et al., 2019) are shown in the Supplementary Material in Figures S1, S2 and S3. All simulations are run at a spatial horizontal resolution of 15 km. The basic dynamics of the melt-elevation feedback and the GIA feedback are well captured at this resolution, which allows to explore the parameter space effectively. However, a lot of features of the complex flow of outlet glaciers are not captured at this resolution.

Table 1. Parameters used in experiments

Name	Parameter	Value
ΔT	Temperature increase	1.5, 2, 3 K
Γ	Atmospheric temperature lapse rate	5 – 7 K/km
ν	Mantle viscosity	$1 \times 10^{-19} - \times 10^{21}$ Pa·s

2.2.2 Choice of model parameters

We chose to vary along three main parameters. On the one hand, we vary the strength of the melt-elevation feedback by varying the atmospheric temperature lapse rate Γ between 5 K/km and 7 K/km. Many ice-sheet models use the free air moist adiabatic lapse rate (MALR), which ranges between 6-7 K/km (Gardner et al., 2009) for high humidity, but assumed to be higher in cold temperatures when the air is dry (Fausto et al., 2009). However, the mean slope lapse rates measured in Greenland and on other ice caps in the Arctic tend to be lower than the MALR and show seasonal variation (Fausto et al., 2009; Gardner et al., 2009; Steffen and Box, 2001; Hanna et al., 2005). By using spatially and temporally constant lapse rates between 5-7 K/km we try to cover a realistic range in lapse rates.

In addition, the response time and strength of the bedrock to changes in ice load is determined by the mantle viscosity ν , varied between 1×10^{19} Pa·s and 5×10^{21} Pa·s. This range is larger than the values of the upper mantle viscosity given in the literature, which still range over more than two order of magnitude over Greenland alone, usually around $1 \cdot 10^{20}$ Pa·s to $5 \cdot 10^{21}$ Pa·s, but local values from $1 \cdot 10^{18}$ Pa·s to $1 \cdot 10^{23}$ Pa·s cannot be ruled out (Tosi et al., 2005; ?; Mordret, 2018; Khan et al., 2016; Wahr et al., 2001; Peltier and Drummond, 2008; Larour et al., 2019; Le Meur and Huybrechts, 1996, 1998; Milne et al., 2018; Fleming and Lambeck, 2004; Lecavalier et al., 2014; Lambeck et al., 2014; Lau et al., 2016). Ice retreat itself is affected by the temperature anomaly, here varied between 1.5 K and 3.0 K global warming (note the arctic amplification of 150 % leading to higher local temperature anomalies).

3 Results

Here, we analyze how the strengths of the melt-elevation feedback and the GIA feedback influence the long term dynamics of the Greenland Ice Sheet in PISM simulations.

3.1 Temporal evolution of ice volume under temperature forcing depending on atmospheric lapse rate and mantle viscosity

The ice losses in simulations with applied warming are affected by both, the amplifying melt-elevation feedback and the mitigating GIA feedback. The interaction of both feedbacks allows for a variety of dynamic regimes, depending on the amount of warming on the one hand and the parameters describing the feedback strength on the other hand.

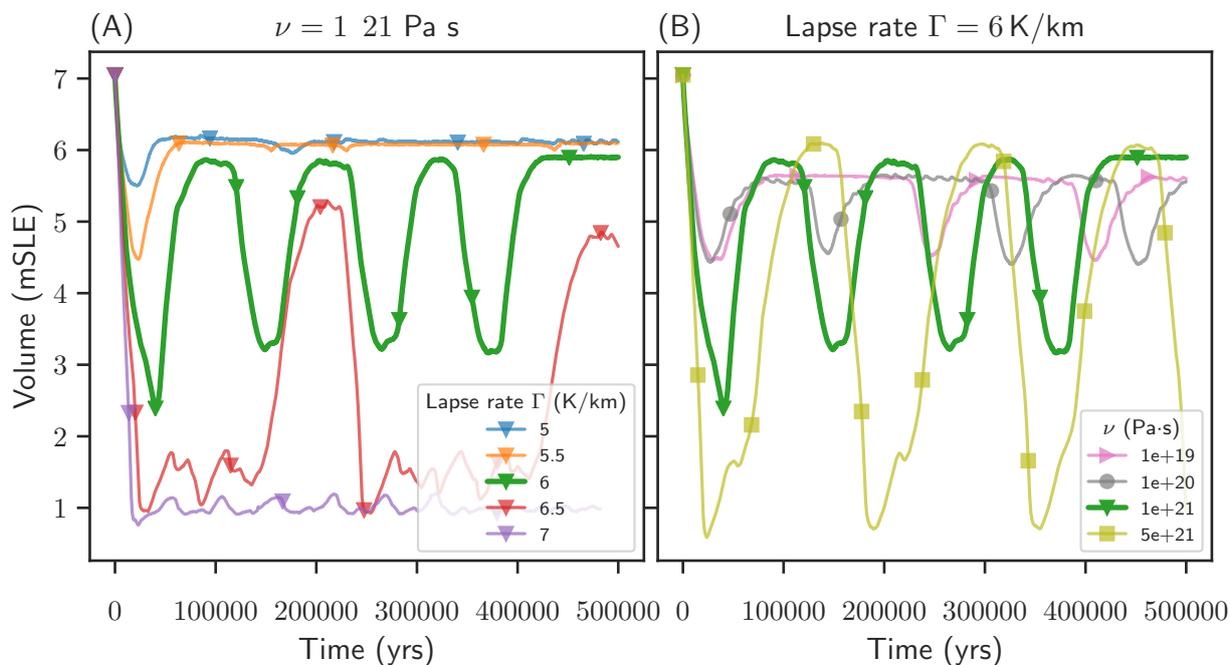

Figure 2. Temporal evolution of Greenland Ice Sheet volume at a temperature anomaly of $\Delta T = 2\text{K}$. Depending on the atmospheric temperature lapse rate (between 5 and 7 K/km) (A) and on the mantle viscosity (between 1×10^{19} and $5 \times 10^{21} \text{ Pa}\cdot\text{s}$) (B) distinct regimes of dynamic responses are observed, including recovery, oscillations and permanent of ice volume.

At a given temperature anomaly (here $\Delta T = 2\text{K}$) and a given mantle viscosity (here $\nu = 1 \times 10^{21} \text{ Pa}\cdot\text{s}$), both, the rate and magnitude of the initial volume loss increase with increasing air temperature lapse rate, i.e. a stronger melt-elevation feedback (see Figure 2 (A)). With a lapse rate of $\Gamma = 5 \text{ K/km}$, at the low end of the tested range, a recovery after an initial ice loss is observed, the ice sheet loses approx 1.5 m sea-level equivalent in volume, before stabilizing at 6 m SLE after approx. 50 kyr (1 m SLE corresponds to approx. 361 800 Gt of ice). With an increasing lapse rate and thereby increasing strength of the melt-elevation feedback the ice volume may still recover after a stronger initial loss. At sufficiently high lapse rates the recovered state is not stable on long time scales. A self-sustained oscillation of repeated ice losses and gains is observed for $\Gamma = 6 \text{ K/km}$ with an oscillation time scale of approx. 109 kyr. Increasing the lapse rate even further, to $\Gamma = 7 \text{ K/km}$ does not allow the ice to recover at all, the ice volume is permanently lost.

Here, depending on the value of the lapse rate Γ three qualitatively different response regimes are observed, (i) recovery, (ii) self-sustained oscillation, and (iii) permanent ice loss.

In contrast a constant lapse rate of $\Gamma = 6 \text{ K/km}$, a warming of $\Delta T = 2\text{K}$ and varying mantle viscosities between $\nu = 1 \times 10^{19} - 5 \times 10^{21} \text{ Pa}\cdot\text{s}$ lead to self-sustained oscillations (ii) in the ice sheet volume independently of the value of the mantle viscosity (see Figure 2 (B)). The variations in mantle viscosity do not change the dynamic regime qualitatively, they affect however the time scale and the amplitude of the observed oscillations. Large values for the mantle viscosity are associated with

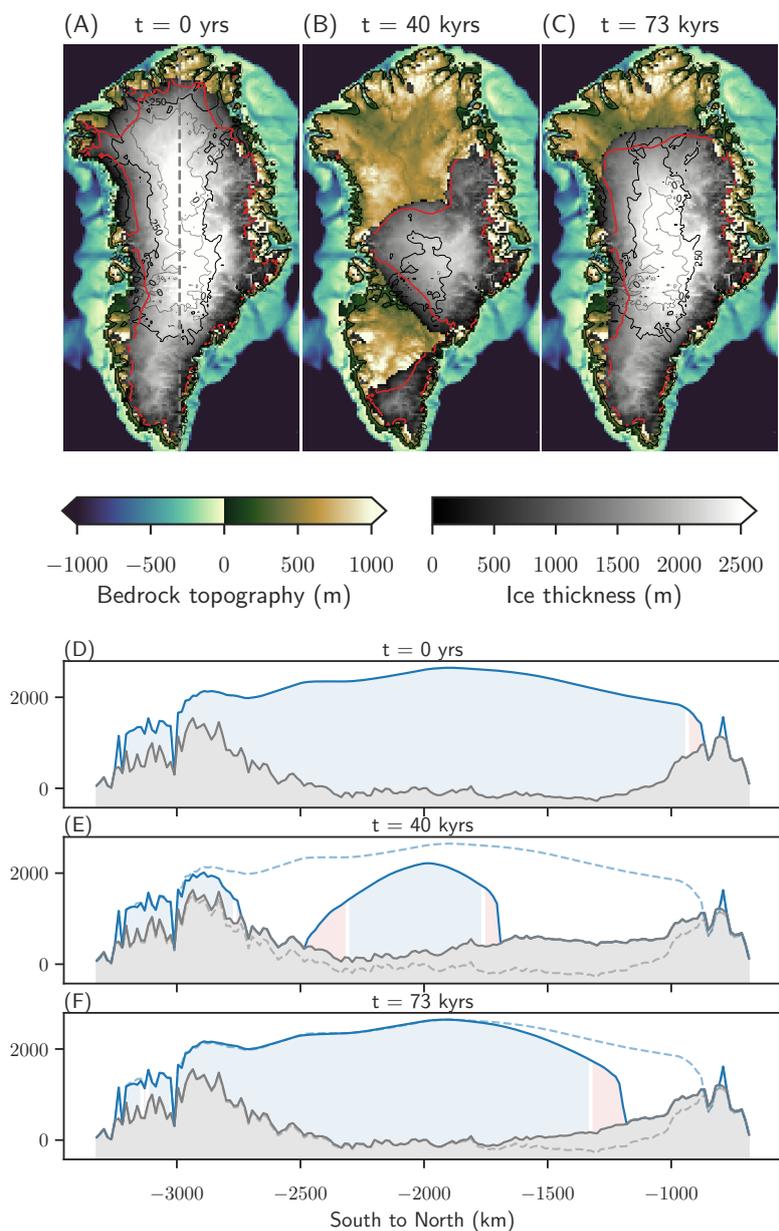

Figure 3. Spatial distribution of ice thickness at a temperature anomaly of $\Delta T = 2\text{K}$ for the parameters $\nu = 1 \times 10^{21} \text{ Pa} \cdot \text{s}$, $\Gamma = 6 \text{ K/km}$. Maps and cross-sections of the bedrock topography and ice thickness show the initial state at the start of the simulation (A,D), the state with minimal volume after 40 kyrs (B,E) and the recovered state after 73 kyrs (C,F). The red outline and the red shaded areas indicate the ablation regions. The dashed lines in (E) and (F) show the initial topography of the ice sheet.

a smaller response time scale of the GIA and thereby allow for larger initial ice losses and large amplitudes of oscillation. The amplitude, here taken as the difference between the maximal and the minimal volume after an initial ice loss, increases from 1.2 m to 5.5 m by increasing the mantle viscosity from $1e+19 \text{ Pa}\cdot\text{s}$ to $5e+21 \text{ Pa}\cdot\text{s}$.

The observed oscillations in ice sheet volume (regime ii) are not perfectly periodical, therefore the concepts of periodicity or frequency cannot be directly applied. This framing would require that the physical state of the ice sheet, regarding not only its volume but also spatially resolved variables like thickness distribution, velocity fields, the state of the solid earth and the climate, return to exactly the same state after one oscillation period. Instead we here use a power spectrum analysis to estimate the characteristic time of oscillation. The oscillation times in this study vary between 79 kyrs (for $\Delta T = 3 \text{ K}$, $\nu = 1 \cdot 10^{21} \text{ Pa}\cdot\text{s}$ and $\Gamma = 5.5 \text{ K/km}$) and 250 kyrs (for $\Delta T = 2 \text{ K}$, $\nu = 1 \cdot 10^{21} \text{ Pa}\cdot\text{s}$ and $\Gamma = 6.5 \text{ K/km}$). An even longer oscillation time of 333 kyrs is found for $\Delta T = 1.5 \text{ K}$, $\nu = 1 \cdot 10^{19} \text{ Pa}\cdot\text{s}$ and $\Gamma = 6.0 \text{ K/km}$, it is however seemingly an outlier: the ice sheet volume seems to recover and reach a permanently stable plateau, but after 250 kyrs a decline in ice-sheet volume is re-initiated. The oscillation times do not seem to show a clear dependence on the values for warming, lapse rate or mantle viscosity.

The spatial configuration of the ice thickness, the bedrock topography and the equilibrium line, separating the accumulation from the ablation region in response to warming is visualized for one example simulation in the oscillation regime (ii), with the parameters $\Delta T = 2 \text{ K}$, $\nu = 1 \times 10^{21} \text{ Pa}\cdot\text{s}$ and $\Gamma = 6 \text{ K/km}$. We choose three points in time, representing the initial state, the state with minimal ice volume and the oscillation maximum, a recovered state which is unstable on long time scales (see Figure 3). The time evolution of the volume is depicted by the thick green curve in Figure 2. During the retreat phase, the mass loss of the ice is initiated from the north of the ice sheet. The area and volume of the ice sheet decrease and reach a minimal value after approx. 40 kyrs, with a remaining ice dome over central Greenland and a second smaller ice patch over the southern tip of Greenland. This ice loss is accompanied by an uplift of the bedrock which is most prominent in areas with complete ice loss. The maximal ice thickness decreases from 2940 m to 2270 m in the minimal volume state, attained in the eastern region of the ice larger ice dome. The maximal bedrock uplift of 740 m is found in the northern region where the most ice is lost. The minimal state is also characterized by an increase in relative ablation area, 29% compared to 24% in the initial state. The maximal relative ablation area of 31% is reached approx. 500 years before the minimum of the volume is reached. Eventually, the accumulation area expands and allows the ice sheet to regrow. However, the maximally recovered ice sheet differs from the initial state in area, thickness distribution, accumulation area, and bedrock topography (see Figs. 3 C and F). In particular the ice sheet extends much less to the north than in the initial state. The precipitation field is assumed to be constant in time, there is no feedback between the ice sheet topography and the precipitation pattern.

3.2 Competing positive melt-elevation and negative GIA feedbacks

Here we explore the competing feedbacks by varying the parameters, which determine the relative strengths of the involved feedbacks, simultaneously.

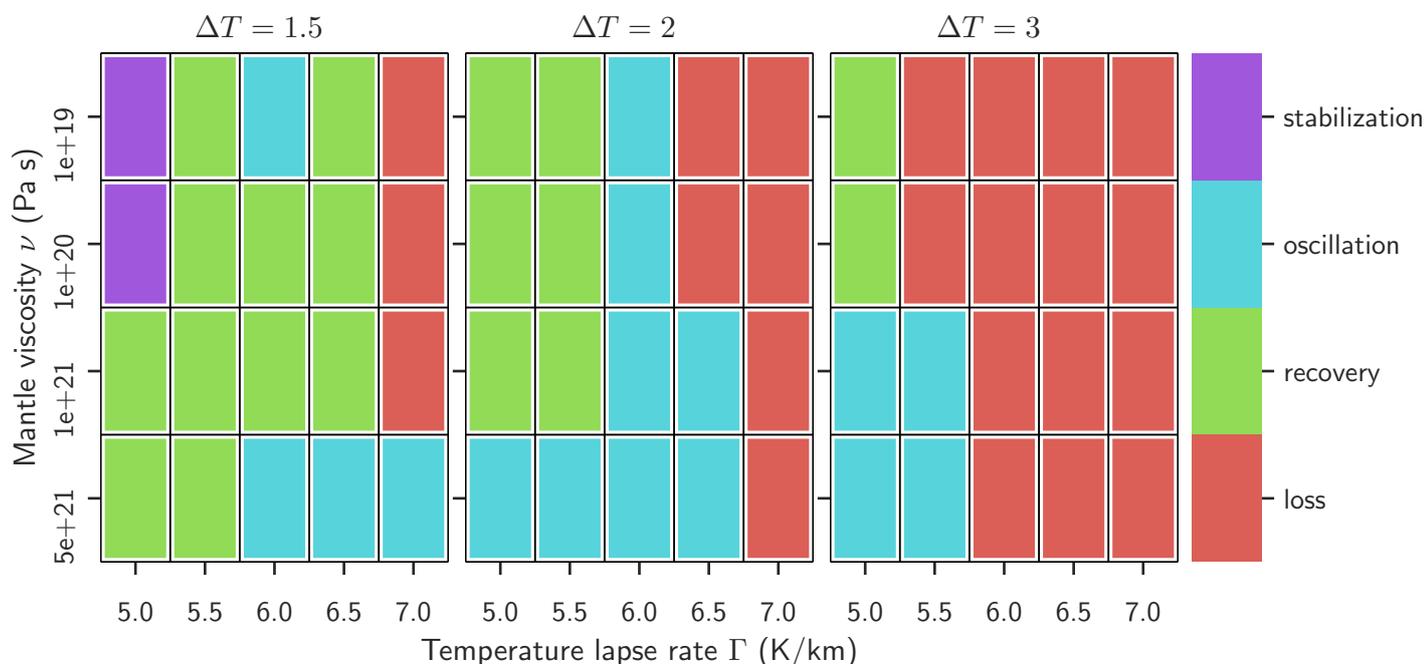

Figure 4. Dynamical regimes of Greenland ice sheet evolution for three different warming temperatures, $\Delta T = 1.5$ K, 2 K, and 3 K. The evolution regime of the Greenland Ice Sheet volume is indicated by the color code. Purple indicates immediate stabilization to a stable state, which preserves more than 90 % of the initial ice sheet volume, without passing a minimum. Green indicates, that the ice sheet volume recovers permanently after passing a minimum first. Blue indicates, that the ice sheet volume does not recover permanently, but shows self-sustained oscillations on a long time scale instead. Red indicates a permanent loss of ice sheet volume.

3.2.1 Dynamic regimes

To gain a better understanding of the dynamic regimes of the GrIS we tested the long-term response of the ice-sheet volume to warming in the full-factorial parameter space $\Delta T, \Gamma$ and ν with values given in Table 1. As stated above in Section 3.1 four qualitatively different response regimes can be distinguished: (o) Direct stabilization into a new equilibrium state which preserves 90% or more of the initial ice volume. (i) Recovery to a stable state after an initial ice loss. (ii) Self-sustained oscillations and (iii) Irreversible loss of a large portion of the ice.

With increasing temperature anomalies ΔT a larger portion of the parameter space experiences irreversible ice loss (iii) (Figure 4). For a warming temperature of 3 K for example, irreversible ice loss is observed for lapse rates greater or equal than 6 K/km for all mantle viscosities and for 5.5 K/km for mantle viscosities lower or equal to $1e+20$ Pa·s.

Moreover, increasing temperature lapse rate promotes irreversible ice loss, for instance at $\Gamma = 7$ K/km, irreversible ice loss occurs for warming temperatures of 2 K or warmer, regardless of the choice for the mantle viscosity (see Figure 4) and also for most simulations with $\Delta T = 1.5$ K.

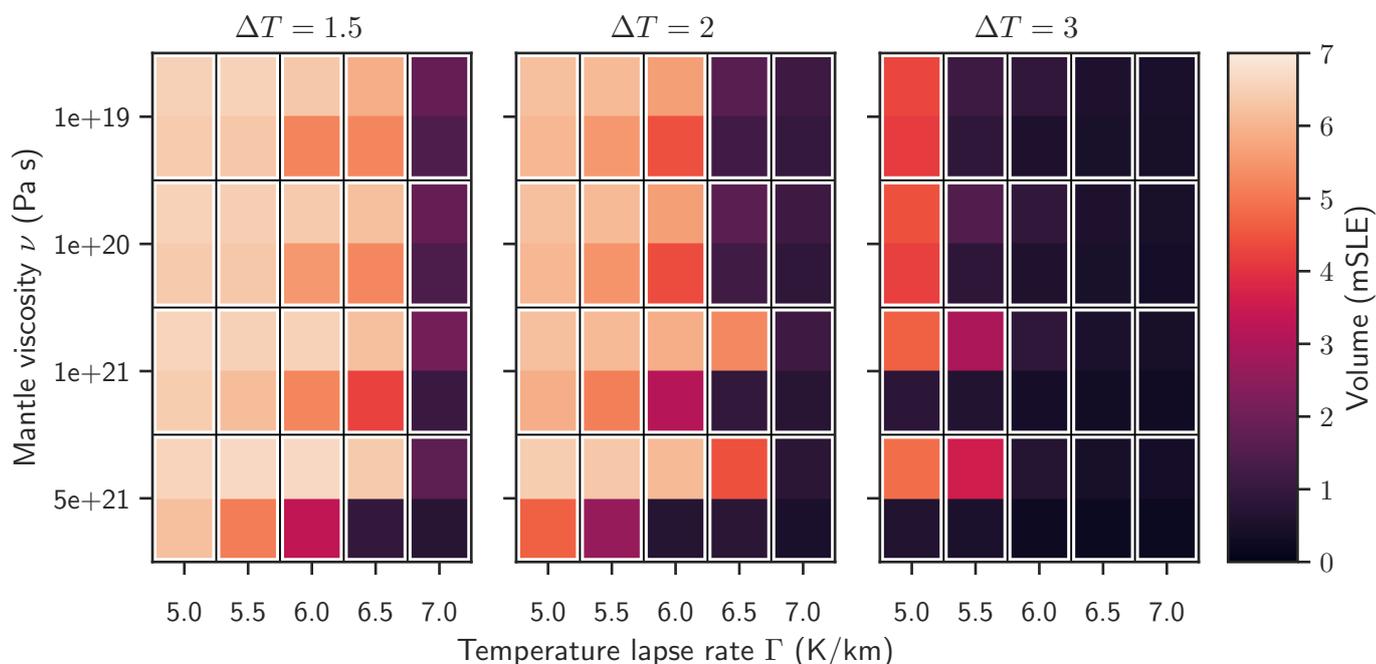

Figure 5. Minimal and maximal volume after initial ice loss for three different warming temperatures, $\Delta T = 1.5 \text{ K}$, 2 K , and 3 K . Two pixels represent the minimal (lower) and the maximal (upper) long-term volume for each parameter combinations. The minimal and maximal long-term volume is defined by the minimum or the maximum of the volume after passing the initial minimum. A significant difference between the minimal and the maximal volume indicates oscillation.

Direct stabilization without going through a minimum (o) is only realized for the lowest temperature anomaly $\Delta T = 1.5 \text{ K}$ and at the lowest lapse rate $\Gamma = 5 \text{ K}$. While recovery or stabilization are the most prevalent regimes for low warming temperatures (1.5 K) in the tested parameters space, the oscillatory regime is realized most often at temperature anomalies of 2 K . High mantle viscosities promote oscillations of the ice sheet volume as they lead to a slower response of the bedrock to changes in ice loss and thereby allow for a stronger retreat phase and thereby a faster initial ice loss with warming, as seen in Fig. 2. On the other hand, the more pronounced retreat initiates a strong bedrock response which supports the recovery. However, the recovered state is not in equilibrium with the bedrock, and thereby a self-sustained oscillation can be triggered.

3.2.2 Minimum and maximum ice volume for recovery or oscillation regimes

The long-term response of the Greenland Ice Sheet volume to temperature anomalies can be characterized by the minimal and maximal long-term volume, defined as the minimal and maximal volume attained after passing an initial minimum. In the dynamic regimes of stabilization, recovery, and permanent ice loss the minimal and maximal long-term volumes are therefore almost identical. The absolute values of the minimal and maximal long-term volume determine how much ice is lost and the difference between them shows how large the amplitude of the oscillation is. The minimal and maximal long-term volumes are

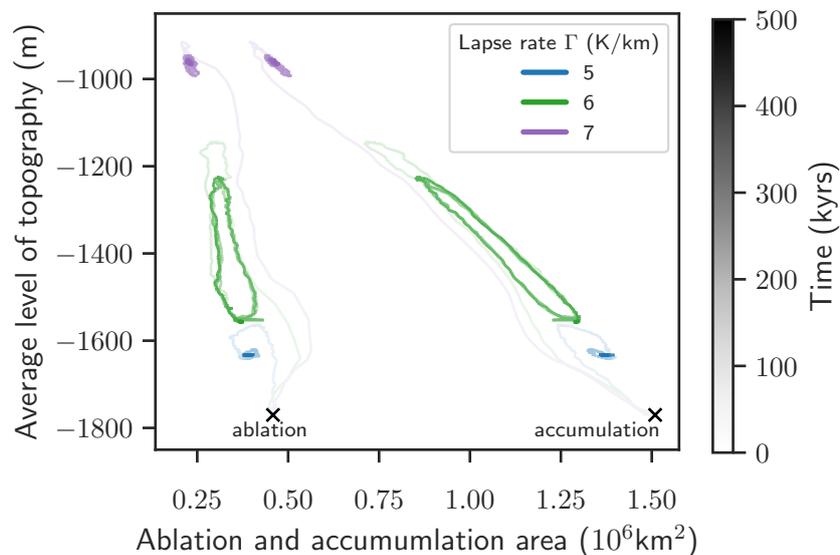

Figure 6. State space trajectories for different regimes for the three different lapse rates $\Gamma = [5, 6, 7]$ K/km. The curves represent the average height of the bedrock topography vs. the ablation and the accumulation area. Blue: Lapse rate $\Gamma = 5$ K/km, recovery of the ice volume. Green: Lapse rate $\Gamma = 6$ K/km, oscillation of the ice volume. Purple: Lapse rate $\Gamma = 7$ K/km, irreversible loss of the ice volume.

visualized in Figure 5. Here, two values are shown for each parameter combination. The upper pixels represent the maximum long-term volume, while the lower pixel represents the minimum long-term volume. A comparison to the regime shown in Figure 4 reveals that both volumes are high if the ice volume is stabilized directly or recovers, and both volumes are low if the ice is permanently lost. Oscillations are characterized by a significant difference between the minimal and maximal long-term volume. Generally, the absolute values for either stabilized, oscillating or lost volume decrease with increasing warming. The amplitude of oscillations is highest for high mantle viscosities, since the slow response time associated with high mantle viscosities allows for more ice loss but also for a stronger recovery.

3.3 State space trajectories

Here we analyze the different dynamic regimes of the Greenland Ice Sheet via their trajectories through state space. The full state space of an ice sheet has a very high dimensionality and even with the simplifications made by numerical modelling, the full state space remains inaccessible. Here we choose the projection of the state to three state variables: The temporal evolution of the topography altitude of the glaciated areas on the one hand and the ablation or accumulation area of the ice sheet on the other hand. In both cases the variables are averaged over glaciated areas rather than over a fixed area (e.g. the initial ice sheet area), because this is where they affect the ice sheet. For instance the bedrock uplift in a region which has (permanently) lost its ice does not take part in the feedback as described in Fig. 1. The average topography altitude can change either via glacial isostatic adjustment while the ice sheet area is constant or by changing the ice sheet area at constant topography or

a combination of those two processes. The ablation or accumulation area can either change through changes in the ice-sheet area at constant climatic mass balance or via changing the climatic mass balance but keeping the ice-sheet area constant (or a combination of those two processes).

We interpret the topography altitude as a measure of the GIA feedback and the accumulation and ablation area as a measure for the climatic processes.

We can distinguish three different "phase space trajectories" for the different regimes: recovery after an initial ice loss (i), oscillation (ii) and ice-sheet collapse (iii). All of the simulations shown here are at $\Delta T = 2$ K and with the mantle viscosity of $\nu = 1 \times 10^{21}$ Pa·s.

For $\Gamma = 5$ K/km (blue curves in Figure 2 (A) and Figure 6), the ice sheet is in the recovery regime. Both, the accumulation / ablation areas and the average topography diverge the least from the starting point compared to the other simulations. The trajectories for both accumulation and ablation area spiral quickly into a fixed point. The trajectory for the ablation area follows a counterclockwise spiral while the trajectory for the accumulation area follows a clockwise spiral. The trajectory for the ablation area starts out almost vertically upwards, only little change in the ablation area is observed. The accumulation however shrinks while the bedrock elevation rises. The turning point is characterized by a shrinking ablation area, a rising accumulation area and a depression in bedrock elevation. Here, changes in accumulation area seem to be more important than the changes in the ablation area and to drive the dynamics. Moreover, the ablation and the accumulation area do not seem to be independent, they show, as expected, an anticorrelation.

For $\Gamma = 6$ K/km (green curves in Figure 2 (A) and Figure 6) the ice sheet is in the oscillation regime. The trajectories spiral into a closed loop rather than a fixed point. Again, the trajectory with the ablation area goes counter-clockwise while the trajectory for the accumulation area goes clockwise. In absolute terms the accumulation area changes more drastically than the ablation area, an indication that the change in accumulation area drives the ice loss. The total change in ice-sheet area is reflected through the sum of ablation and accumulation area. Even though the trajectories form a closed loop in this simulation, there is no perfect periodicity. In particular the first loop in the trajectory is larger than the subsequent quasi-periodic behavior.

The atmospheric lapse rate of $\Gamma = 7$ K/km (purple curves in Figure 2 (A) and Figure 6) leads to irreversible ice-sheet collapse under these parameters. The trajectories approach again a fixed point. Both the accumulation and the ablation area are smallest, compared to the other two lapse rate simulations, indicating that the total area of the ice sheet is also small. Again, the absolute change in accumulation area is more drastic than the change in ablation area. In addition, the change in average level of bedrock topography is highest. As indicated beforehand, this is both related to the bedrock uplift (most ice loss allows for the strongest uplift) as well as to the fact that the remaining ice retreats to high altitude mountainous areas with a lot of precipitation and comparatively low temperatures.

The trajectories of the different regimes do not intersect, suggesting that the phase space is well represented.

4 Discussion

In this manuscript, we show how the negative glacial isostatic adjustment feedback (connecting ice sheet and solid Earth) can counteract the positive melt-elevation feedback (connecting atmosphere and ice sheet) and thus the long-term ice loss of the Greenland Ice Sheet under warming temperatures. The interaction of both feedbacks determines the dynamic regime and the stability of the Greenland Ice Sheet. Depending on the individual feedback strengths, expressed through mantle viscosity and atmospheric temperature lapse rate respectively, we find distinct regimes for the evolution of the ice volume: the transition to a new steady state, recovery after an initial ice loss, self-sustained quasi-periodic oscillations or irreversible ice-sheet collapse. Although it is not explicitly studied here, drastic changes in the ice volume of the Greenland Ice Sheet would have implications for the global earth system via global sea level rise, changes in the planetary albedo, and changes in the atmospheric and oceanic circulation patterns as the Jetstream or the Atlantic Meridional Overturning Circulation (AMOC).

The strength of the melt-elevation feedback impacts the vulnerability of the Greenland Ice Sheet to temperature increases: Varying the feedback strength through the atmospheric lapse rate from 5 K/km to 7 K/km increases the probability of permanent ice loss for global mean temperature anomalies $\Delta T \geq 1.5$ K, assuming 150% of arctic amplification. Increasing the mantle viscosity from 1×10^{19} Pa·s to 5×10^{21} Pa·s increases the likelihood for self-sustained oscillations and their corresponding amplitude. The characteristic period of oscillation is in the order of 100 kyrs, which is rather independent of both, mantle viscosity or temperature lapse rate. However, in case of recovery the associated characteristic response time seems to increase with increasing lapse rates or mantle viscosities.

4.1 GIA feedback in different contexts

The impact of the GIA feedback on ice-sheet dynamics has been studied in different contexts. Marine terminating glaciers and ice shelves are particularly sensitive to glacial isostatic rebound, as it can influence the position of the grounding line and how exposed the ice shelf or the glacier front is to warm ocean water (Larour et al., 2019; Whitehouse et al., 2019). Observational evidence pointing to an overshoot and readvance of the grounding line in the Ross Sea, Antarctica, can be explained by the viscous response of the solid Earth to changes in ice load within a confined range of mantle viscosities (Kingslake et al., 2018). Feldmann and Levermann (2017) showed, that the complex interplay of time scales associated with the surge, buildup and stabilization feedbacks could explain Heinrich-like events.

4.2 GrIS ice volume oscillations in the context of the Earth System

While oscillations of ice volume have already been discussed in the context of marine ice sheets (Antarctic Ice Sheet, Laurentide Ice Sheet) (Bassis et al., 2017), we here find that the interaction of the melt-elevation feedback and the GIA feedback alone can promote an oscillatory dynamic response.

However, small oscillations in the GrIS ice volume seem to appear in simulations with a coupled ice-sheet and regional climate model (Petrini et al., 2021). Although the oscillatory regime is not studied explicitly by Petrini et al., its appearance indicates that this dynamic regime is unlikely to be an artifact of our particular experimental design.

The oscillation time are of the same order of magnitude as the time scale of Earth's glaciation cycle, with a dominant period of 41 kyrs before and a period of 100kys after the Mid-Pleistocene Transition 1.25–0.7 million years ago (Abe-Ouchi et al., 2013; Willeit et al., 2019). While the onset and the termination of glaciation are driven by changes in insolation, climate and earth surface albedo (Ganopolski and Calov, 2011) our results offer a new perspective. The identified oscillatory regime reveals
5 a possible mode of internal climatic variability in the Earth system on time scales on the order of 100 kyrs that may be excited by or interact with orbital forcing, glacial cycles and other slow modes of variability (Ghil and Lucarini, 2020). As such, this oscillatory mode could be relevant in the long-term Earth system response (on the order of 100 kyrs) to anthropogenic carbon emissions (Talentó and Ganopolski, 2021).

Our findings suggest a sequence of dynamic regimes of the Greenland Ice Sheets on the route to destabilization under
10 global warming, within a certain range of lapse rate coefficients: from recovery, via quasi-periodic variations in ice volume to irreversible ice-sheet collapse. This transition might be similar to destabilization scenarios via oscillatory instabilities which have been revealed for other tipping elements in the climate system, such as the Atlantic Meridional Overturning Circulation (AMOC) (Alkhayouon et al., 2019). A relevant area of future research will be to develop a deeper understanding of such ice sheet destabilization routes via the concept of bifurcations (e.g., Hopf and fold bifurcations) in the context of dynamical systems.
15 The interplay between an amplifying and a mitigating feedback contributes to our understanding of the long-term stability and the resilience of the Greenland Ice Sheet. Therefore we need to identify the most important underlying physical processes and the interactions of the feedbacks at play.

4.3 Limitations

This study is based on the results of the ice sheet model PISM coupled to simple models which capture the melt-elevation
20 feedback, namely the positive degree day approach together with an atmospheric temperature lapse rate, and the GIA feedback, namely the Lingle-Clark model. The relative computational efficiency of those models allows us to conduct an ensemble of long-term simulations over 500,000 years exploring different parameter values characterizing the individual feedbacks and warming. This approach fits the conceptual research question of this study.

The Lingle-Clark approach assumes a flat earth with two layers, one elastic and one viscous layer, in contrast to more
25 sophisticated solid Earth models. It also does assume horizontally constant Earth structure and does not solve the self-consistent sea-level equation. However, the relative importance of discharge and melt at the ice-ocean interface decreases with ongoing warming, as the tidewater glaciers retreat and the ice-ocean interface shrinks (Aschwanden et al., 2019). With ongoing coupling efforts between ice-dynamics models and process based solid Earth models, this study is a first step to assessing the importance of the GIA feedback for the stability of the Greenland Ice Sheet.

30 While the design of the study was chosen in order to allow for long experiments and to cover parts of the parameter space (ΔT , Γ , and ν), it is also one of the main limitations of the study. The coarse resolution of the ice sheet model does not adequately resolve the flow patterns in outlet glaciers, therefore underestimating dynamical ice losses. Moreover, the parameters which govern the ice dynamics, although uncertain, were not varied (Zeitz et al., 2020).

The choice of the positive degree day (PDD) method in order to compute the climatic mass balance introduces a tends to underestimate the melt area for present climate, while at high temperatures PDD tends to overestimate melt. Moreover, the temperature anomaly is applied in a spatially and temporally constant way and the precipitation pattern remains fixed. So far, scenario-based projections of future global warming are limited until the year 2300, with projections of the temperature evolution and changes in climatic mass balance over the Greenland Ice Sheet as results from regional climate models only available until the end of this century. The aim here, however, is not to present scenario-based projections of future ice losses but rather to study the distinct dynamical states in the "deep future" of the Greenland Ice Sheet in a fundamental way.

5 Conclusions

Here we present an analysis of the dynamic regimes in the deep future of the Greenland Ice Sheet. Depending on the amount of warming and the values of the parameters describing the strength of the melt-elevation feedback and the GIA feedback we find that four different dynamic regimes can be realized: 1) Direct stabilization into a new equilibrium state which preserves 90% or more of the initial ice volume, 2) Recovery to a stable state after an initial ice loss, 3) Self-sustained oscillations, and 4) Irreversible loss of a large portion of the ice. Our model configuration with parameterized melt-elevation feedback and a fast computation of the leading-order GIA effects allows for studying an ensemble of glacial time-scale simulations and provides insight into how the interaction of feedbacks impacts the dynamics of the complex Earth system with implications for Earth system stability and resilience.
