15 **Abstract.** Leaching of dissolved organic carbon (DOC) from soils to the river network is an important
16 component of the land carbon (C) budget. At regional to global scales, its significance has been estimated
17 through simple mass budgets, often using multi-year averages of observed fluvial DOC fluxes as proxy of DOC
18 leaching due to the limited availability of observations of the leaching flux itself. This procedure leads to a
19 systematic underestimation of the leaching flux because of the reactivity of DOC during fluvial transport.
20 Moreover, this procedure does not allow to reveal spatio-temporal variability in DOC leaching from soils, which
21 is needed to better understand the drivers of DOC leaching and its impact on the local soil C budget. In this
22 study, we use the land surface model ORCHILEAK to simulate the terrestrial C budget including leaching of
23 DOC from the soil and its subsequent reactive transport through the river network of Europe. The model
24 performance is not only evaluated against the sparse observations of DOC leaching, but also against the more
25 abundant observations of fluxes and reactivity of DOC in rivers, providing further evidence that our simulated
26 DOC leaching fluxes are realistic. The model is then used to simulate the spatio-temporal patterns of DOC
27 leaching across Europe over the period 1972 to 2012, quantifying both the environmental drivers of these
28 patterns as well as the impact of DOC leaching on the land C budget. Over the simulation period, we find that on
29 average 14.3 TgC yr⁻¹ of DOC is leached from land to European rivers, which is only about 0.6% of the
30 terrestrial net primary production, a fraction about one order of magnitude lower than reported for tropical river
31 networks. Of the DOC leaching, on average 12.3 TgC yr⁻¹ is exported to the coast via the river network, the rest
32 being respired in transit. DOC leaching presents a large seasonal variability, with a maximum occurring in
33 winter and a minimum in summer, except for the Northern most part of Europe where the maximum occurs in
34 spring due to the snow melt. DOC leaching rate is generally lower in warm and dry regions, and higher in cold
35 and wet regions of Europe. Furthermore, runoff, and the ratio between runoff from shallower flow paths vs. deep
36 drainage and groundwater flow, is the main driver of the spatial variation of DOC leaching. Temperature, as a
37 major control of DOC production and decomposition rates in the soils, plays only a secondary role.

38 **1 Introduction**

39 Land ecosystems are an important carbon (C) sink which absorbs about one fourth of anthropogenic CO₂
40 emissions and stores it in increasing biomass and soil carbon pools (Friedlingstein et al., 2020). This terrestrial
41 sink mitigates the growth rate of atmospheric CO₂ and thus plays an important role in regulating climate change
42 (Ciais et al., 2013). However, the efficiency of that sink is partly alleviated by the permanent, lateral leaching of
43 C from soils, through the river network down to the ocean (Regnier et al., 2013). An accurate understanding of
44 lateral carbon fluxes through the river network is thus necessary to better understand the global C cycle and to
45 inform policies of climate change mitigation (Le Quéré et al., 2018).

46 The identification of riverine C transfers as a key component of the continental C budget constituted an
47 important paradigm shift in our understanding of the global C cycle (Cole et al., 2007). More recently, riverine C
48 cycling was also shown to be affected by anthropogenic perturbation and thus to be an element of the
49 anthropogenic CO₂ budget (Regnier et al., 2013; Le Quéré et al. 2015). Anthropogenic perturbations of riverine
50 C fluxes are manifold and comprise direct impacts through changing C and nutrient inputs following land-use
51 change and agricultural activities, wastewater discharge, and hydraulic management (e.g. Tian et al., 2015;
52 Lauerwald et al., 2020; Hastie et al., 2021; Maavara et al., 2017). There are also indirect impacts following
53 climate change and changes in atmospheric composition. Together, these perturbations have accelerated the
54 turnover of C along the terrestrial-inland water continuum. The terrestrial C sink, which is classically estimated
55 without taking into account the C exports through the river network, is thus generally overestimated (Regnier et
56 al., 2013; Lauerwald et al., 2020).

57 The integration of riverine C transfers into the terrestrial C budget requires the quantification of the amount of C
58 lost from soils to the river network. Due to the scarcity of observational data, this flux is not easy to determine
59 based on empirical methods. At global scale, this flux was estimated through budget closure based on estimates
60 of riverine C exports to the coast and estimates of C losses to the atmosphere and aquatic sediments during
61 transport. The existing global estimates of these soil C exports to the river network, as synthesized by Drake et
62 al. (2018), range from 1.1 to 5.1 PgC yr⁻¹ – a huge uncertainty range reflecting the limitations of empirical
63 estimation approaches and the paucity of underlying data. Over the past decade, a new generation of land surface
64 models (LSMs) have been developed, which represent the export of C from soils to the river network, and in
65 some cases even the transport and cycling of these terrestrial C loads along the river network down to the coast
66 (Smith et al. 2010; Kicklighter et al. 2013; Tian et al., 2015; Lauerwald et al., 2017; Nakhavali et al., 2018).
67 With the exception of the study by Tian et al. 2015, all these studies focus on the lateral export of dissolved
68 organic C (DOC) which is a product of the incomplete decomposition of plant litter and soil organic carbon
69 (SOC). These mechanistically based models allow to predict the leaching of DOC in unmonitored regions and to
70 assess the spatial and temporal variability which, to date, can only be poorly resolved by empirical methods.
71 Moreover, these approaches link the C exports from soils to the river network to the terrestrial C cycle, and thus
72 allow to directly assess the role of these C exports in the terrestrial C budget, its perturbation through land use,
73 land use change and changes in climate and atmospheric chemistry, and its impact on the terrestrial sink for
74 anthropogenic CO₂ emissions.

75 In this study, we use the LSM ORCHILEAK (Lauerwald et al. 2017), a branch of the IPSL-LSCE LSM
76 ORCHIDEE (Krinner et al. 2005), to quantify the DOC leaching from soils and its effects on the terrestrial C
77 budget in Europe. ORCHILEAK not only simulates the vertical C cycling between vegetation, soils and
78 atmosphere in response to climate, atmospheric CO₂ concentrations, and land use change, but also represents the
79 lateral exports of DOC from soils to the river network as well as the reactive transport of that DOC through the
80 river network. To our knowledge, only one study (Kindler et al., 2011) estimated the soil DOC leaching flux
81 based on runoff and direct observations of DOC concentrations in the soil water for various locations across
82 Europe, and will thus be used for direct evaluation of the simulated leaching fluxes. Further, we evaluate
83 simulated against observed riverine DOC fluxes which are available from different water quality surveys and
84 scientific publications. Assuming a realistic representation of DOC reactivity in the river network, which is to be
85 evaluated against observations as well, this model-data comparison of riverine DOC fluxes represents a valuable,
86 additional possibility to assess the validity of simulated soil DOC leaching.

87 So far, ORCHILEAK has been successfully tested and applied on large, near-natural river systems such as the
88 Amazon (Lauerwald et al. 2017, Hastie et al. 2019, Lauerwald et al. 2020), the Congo (Hastie et al. 2021) and
89 the Lena Rivers with a version also including some specific permafrost related mechanisms (Bowring et al.
90 2019, 2020). In this study, for the first time, ORCHILEAK is applied to, and evaluated for, the European river
91 network which is subject to direct impacts of agricultural land use, in contrast to more natural river basins. For
92 this reason, we devote special attention to manure application as an anthropogenic non-point source of DOC to
93 the river network, while we assume that for the period of simulation (1979-2012), due to quality of sewage water
94 treatment, anthropogenic point sources of DOC are now negligible for most parts of Europe.

95 Making full use of the capabilities of the ORCHILEAK model, we study in detail the spatio-temporal patterns in
96 DOC leaching and its quantitative contribution to the terrestrial C budget across Europe. We investigate how
97 specific climate zones in Europe differ with regard to seasonality in DOC leaching fluxes, which are
98 hypothesized to be controlled by hydrology, litter fall and temperature effects on litter and SOC decomposition.
99 We will further try to quantify the effect of these controls in the different climate zones of Europe. Finally, we
100 strive to find out in which climate zone DOC leaching affects the terrestrial C budget the most.

101 **2 Methodology**

102 **2.1 ORCHILEAK**

103 **2.1.1 Model overview**

104 ORCHILEAK (Lauerwald et al., 2017) is a branch of the model ORCHIDEE (Organizing Carbon and
105 Hydrology in Dynamic Ecosystems) (Krinner et al., 2005), the land surface component of the Institut Pierre-
106 Simon Laplace (IPSL) Earth system model (ESM). ORCHIDEE simulates energy, water and C fluxes between
107 the atmosphere and the land at a global scale. This LSM is based on four sub-modules. The first one, SECHIBA,
108 simulates the energy budget (energy, carbon and water) between the atmosphere and the biosphere as well as the
109 hydrology, which in the default set-up used here, are both represented using a 30 minute time-step. The second
110 sub-module, adapted from the LPJ model (Sitch et al., 2003), represents the dynamics of vegetation distribution
111 on long time scales (1 year), while the third one (STOMATE) simulates the C dynamics in vegetation and soils
112 at a daily to sub-daily step (Krinner et al., 2005). Finally, the fourth sub-module handles the routing of water that
113 is lost via surface runoff and drainage from soils to the ocean through the global river network (Polcher 2003,
114 Guimberteau et al., 2012), for which a daily time-step is used. All processes are simulated on a horizontal model
115 grid, the resolution of which can be adapted to that of the meteorological forcing files. In this study, simulations
116 are run at a spatial resolution of 0.5°. Moreover, in the default set-up, up to 13 plant function types (PFTs; bare
117 soil, eight types of forest, two types of grassland and two types of cropland) can be distinguished for each cell,
118 for which C budgets are simulated individually, while energy and water budgets are simulated at the grid cell
119 level.

120 ORCHIDEE represents the soil C dynamics distinguishing different pools of plant litter and soil organic C over a
121 2 m profile. A branch of ORCHIDEE, called ORCHIDEE-SOM (Camino et al. 2018), added a vertical
122 discretization of these carbon pools over 11 layers and included the representation of DOC production and
123 cycling within the soil column (see section 2.1.2 for more details). ORCHILEAK was built on this branch and
124 accounts for the coupled reactive transport processes impacting the dissolved C inputs from soils to the river
125 network, including both DOC leaching from soils and CO₂ produced by soil respiration, into the hydrologic
126 routing scheme. Besides advective transport of carbon with the water flow, ORCHILEAK simulates the
127 decomposition of DOC during riverine transport, the gas exchange of CO₂ at the interface between the inland
128 water and the atmosphere, and the exchange of C between water column and soil column in inundated
129 floodplains. All those fluxes are closely coupled to the model representation of hydrology that comprises
130 interception of precipitation, throughfall, infiltration, percolation, surface runoff, drainage, and the routing of
131 discharge along the river-floodplain network.

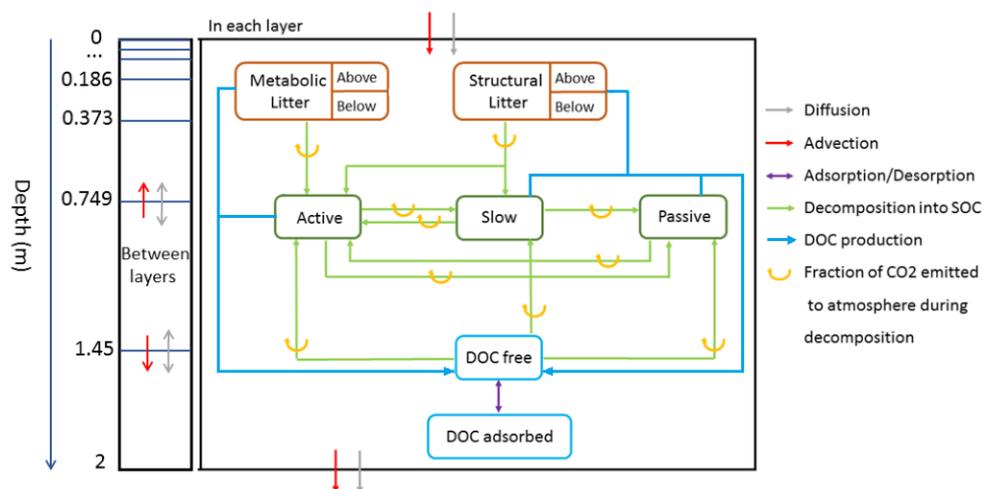

132

133 **2.1.2 Soil carbon module**

134 The soil carbon module of ORCHILEAK (Fig. 1) is derived from the CENTURY soil carbon model of Parton et
135 al. (1988). In the standard scheme (Krinner et al., 2005), C in the soil of each model grid cell, and for each PFT,

136 is represented by four different litter and three different soil organic carbon (SOC) pools with different turnover
 137 rates. The four litter pools correspond to metabolic aboveground and belowground litter, structural aboveground
 138 and belowground litter (Fig. 1). The SOC is subdivided into active, slow and passive pools. In the CENTURY
 139 scheme, C from the decomposed structural litter enters the active and the slow pools with the fraction allocated
 140 to each pools depending on lignin content of the litter, while the entire metabolic litter pool and the remaining
 141 part of structural litter is allocated to the active SOC pool. The SOC pools then feed into each other with the
 142 main C flux going from active to slow and passive to represent microbial decomposition of detrital organic
 143 matter, and a small return flux of slow and passive C back to the active pool to represent implicitly the C supply
 144 in the form of dead microbial biomass.

145
 146
 147
 148
 149

Figure 1. The new version of the soil module of ORCHIDEE-SOM. The left box represents the discretization of the soil column and the transport processes between layers. The right box is a zoom of all the biogeochemical transformation processes that occur in each layer.

150

151 Campoy et al. (2013) updated this scheme with a vertical discretization of distinct SOC and litter pools over a 2
 152 m soil profile represented by 11 layers. Camino et al. (2018) further developed the soil C module by including
 153 an explicit representation of the fate of DOC along this vertically discretized soil profile. Processes accounted for
 154 are DOC production from the decomposition of SOC and litter, decomposition of DOC within the soil,
 155 sorption/desorption of DOC onto/from mineral surfaces, vertical advection and diffusion of DOC through the
 156 soil column, and lateral, advective leaching of DOC out of the soil profile, along with surface runoff and
 157 drainage.

158 The DOC dynamics in the soil is controlled by production, decomposition and transport along the discretized 2
 159 m soil column (equation 1):

$$\frac{dDOC_i}{dt} = \sum (Production_i - Decomposition_i) + F_{A,i} + F_{D,i} \quad (1)$$

160 Where i stand for the index of each layer. Each layer is connected to the adjacent layers by advection F_A and
161 diffusion F_D . The total DOC transport flux is made of an advective component (equation 2) computed as the
162 product of the water flux Q and the DOC concentration (in the i -th layer) and a diffusive component that follows
163 Fick's first law (equation 3):

$$F_A = Q * DOC_i \quad (2)$$

$$F_D = -D * \frac{\partial^2 DOC}{\partial z^2} \quad (3)$$

164 where i stands for the i th layer, z for the depth along the discretized soil profile, and D stands for the molecular
165 diffusion coefficient of DOC.

166 The advective export of DOC to the river network is proportional to the top (first five layers, 4.5 cm) and bottom
167 (11th layer) DOC concentrations, corresponding to water loss fluxes associated to runoff (for near surface) and
168 drainage (for deep). We also apply a Fickian-type transport to represent the effect of bioturbation on DOC
169 profiles, as well as on the solid phase SOC and litter profiles. Therefore, in contrast to advection, which only
170 affects DOC entrained with water losses, bioturbation transports both SOC and DOC across the different layers.
171 In addition, DOC is diffusing along the concentration gradient within the soil solution.

172 The right hand-side of Fig. 1 summarizes the set of production/decomposition processes that occur in each layer.
173 During litter decomposition, a fraction of the C is directly emitted back to the atmosphere as CO_2 while the
174 remainder feeds the active and slow SOC pools:

175

$$CO_2 \text{ respiration}(Litter) = (1 - CUE) * k_L * (1 - \omega_L) * Litter \quad (4)$$

$$Litter \text{ decomposition} = CUE * k_L * (1 - \omega_L) * Litter \quad (5)$$

176 where k_L is the kinetic constant for the litter decomposition (dependent on soil moisture and temperature
177 (Camino et al., 2018)) and ω_L the fraction of litter that is channelled into DOC production (as opposed to
178 particulate soil carbon SOC). This approach of relating DOC production directly to the decomposing litter is
179 inspired by Nakhavali et al., 2018 (following from the ECOSSE model (Smith et al., 2010)) and is a major
180 modification compared to the previous version of soil DOC and POC cycling from Camino et al., 2018. In
181 equations (4) and (5), the partitioning between SOC production and respiration is defined by the carbon use
182 efficiency (CUE).

183 In turn, active SOC is degraded into both slow and passive SOC and the respiration fluxes associated with these
184 processes are also controlled by the CUE (equations 6 and 7, with k_{SOC} as the kinetic constant for SOC
185 decomposition) and ω_{SOC} as the fraction of SOC that is transformed into DOC):

$$CO_2 \text{ respiration}(SOC) = (1 - CUE) * k_{SOC} * (1 - \omega_{SOC}) * SOC \quad (6)$$

$$SOC \text{ decomposition} = CUE * k_{SOC} * (1 - \omega_{SOC}) * SOC \quad (7)$$

186

187 The decomposition of the litter and SOC pools produces a small amount of DOC according to equation 8. The
188 DOC pool is thus fed by seven contributing sources, one for each of the four decomposing litter pools and three
189 from the decomposing SOC pools:

190

$$DOC \text{ production} = k_L * \omega_L * Litter + k_{SOC} * \omega_{SOC} * SOC \quad (8)$$

191 In ORCHIDEE-SOM (Camino et al. 2018), all decomposed litter and SOC which is not respired to CO₂, was
192 first fed into the DOC pools, and only upon the decomposition of that DOC, the non-respired fraction of the
193 decomposed DOC could feed the other SOC pools. Such formulation is in contrast to the adaption of the RothC
194 SOC model in ECOSSE (Smith et al., 2010) and JULES (Nakhavali et al., 2018) that we followed here, where
195 the major exchange of C is between the different litter and SOC pools, and the production of DOC is related to
196 these SOC and litter pools by empirical rate constants, which were fitted to reproduce observed DOC turnover
197 times (Kalbitz et al., 2003, Turgeon, 2008) and DOC concentrations in the soil. The much higher DOC
198 production rates simulated by ORCHIDEE-SOM in its original configuration during preliminary tests over
199 Europe led us to implement the new approach (equations 4-7). While preserving the basic structure of
200 ORCHIDEE-SOM, we thus adapted the model in a way that organic C exchange occurs mainly among the
201 particulate litter and SOC pools, similar to the original Century model, while the production of DOC is
202 dependent on leaching rates as used in ECOSSE. In the modified soil carbon module, we used the parameter ω in
203 Equations (4-7) as a scaling factor that determines how much DOC is produced by the decomposition of litter
204 and SOC. This parameter was calculated after Smith et al. (2010) as the ratio of production of DOC from litter
205 (p_{DOC_L}) and the SOC pools ($p_{DOC_{SOC}}$) to the decomposition rates of litter (k_L) and SOC (k_{SOC}). The initial values
206 for ω were 0.5 % and 3 % for the litter and SOC pools, respectively. Further optimization with regard to
207 reproducing observed soil DOC concentrations led to ω values set at 0.2% for the litter and 1.2% for the SOC
208 pools.

209 Once produced, DOC can then adsorb on particles, and desorb from the adsorbed pool back into free DOC pool
210 following an equilibrium reaction between the dissolved and adsorbed phases. The partitioning is controlled by
211 K_D , the so-called equilibrium partition coefficient (equation 9).

212

$$DOC_{adsorption-desorption \text{ eq}} = K_D * DOC \quad (9)$$

213 Finally, the DOC pool is subject to decomposition according to equation (10) and then partly feeds into the SOC
214 pools (eq. 11).

215

$$CO_2 \text{ respiration}(DOC) = (1 - CUE) * k_{DOC} * DOC \quad (10)$$

$$SOC \text{ production by } DOC = CUE * k_{DOC} * DOC \quad (11)$$

216 **2.1.3 Manure as an additional C source**

217 In Europe, a large fraction of the landscape is dominated by agricultural and grazing activities and manure
218 application represents a significant additional C - in particular DOC- source to the soil in regions dominated by
219 grasslands and croplands. To constrain the C flux from manure infiltrating into the soil, we used the gridded 0.5°
220 resolution input of manure nitrogen (manure-N) applications produced by Zhang et al. (2017) as forcing file.
221 Following the use of that forcing data in the model branch ORCHIDEE-CNP developed by Sun et al. (2021), we
222 assumed that 90% of the total manure-N is in mineral form (i.e. NH_4^+ or NO_3^-) and the remaining 10% is in
223 organic form. To convert the organic manure-N into a manure-C flux, a C:N stoichiometric ratio of 13.7 was then
224 applied (Vuichard et al., 2018). Finally, the particulate and dissolved organic manure-C were assumed to feed
225 the litter and DOC pools, respectively (Fig. S1). Consistent with ORCHIDEE-CNP (Goll et al., 2017), the
226 fractions of particulate and dissolved manure-C were set to 0.9 and 0.1, respectively.

227

228 **2.1.4 Hydrological processes**

229 The representation of hydrological processes is handled in two distinct sub-modules. The first one, the hydrology
230 sub-module, simulates the vertical exchange of water in the atmosphere-vegetation-soil system in each model
231 grid cell, while the second one, the river routing module, simulates the horizontal transfers between grid cells.
232 The hydrology is forced by several meteorological fields such as precipitation and air temperature. In the
233 hydrology module, precipitation is divided into interception and throughfall, the latter being further subdivided
234 into surface runoff and infiltration into the soil. The infiltration rate is controlled by the throughfall rate, the
235 slope of the soil surface and the hydraulic conductivity of the soil which is a limiting factor for infiltration. The
236 distribution of water within the soil is represented by the distribution of soil moisture over the discretized soil
237 profile (de Rosnay et al., 2002, d'Orgeval et al., 2008). The water budget within the soil is thus determined by
238 the infiltration rate, the evaporation and transpiration from the soil, and drainage at the bottom of the soil
239 column. The infiltration rate and percolation through the soil profile are then used to compute the advective flux
240 of DOC (equation 2)

241 The second module deals with river routing and represents the horizontal transfers of water from the soil column
242 to the aquatic system through surface runoff and drainage, and further through the river network and adjacent
243 floodplains (Vorosmarty et al., 2000). Note that ORCHILEAK simulates the occasional inundation in the river's
244 floodplains, where decomposition rates of the different carbon pools (litter, SOC and DOC) differ depending on
245 whether the soil is flooded or not. For a detailed description of its features, please refer to Lauerwald et al.
246 (2017).

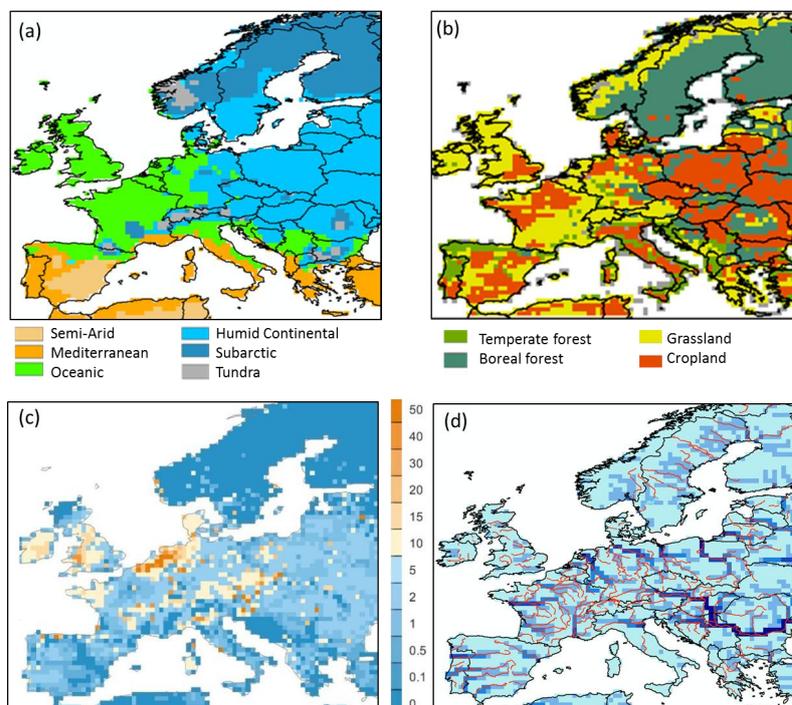

247

248 **2.2 Simulations**

249 **2.2.1 Model set-up**

250 **Model domain, land cover and forcing data.** The simulated model domain extends over the area covered by
251 the EU-27 ($4.1 \cdot 10^6 \text{ km}^2$) between 35°N and 70°N latitude and 10°W and 30°E longitude (Fig. 2). This domain
252 includes 5600 model grid cells at $0.5 \times 0.5^\circ$ resolution and encompasses 6 broad climate zones according to the
253 Köppen-Geiger classification from Peel et al., 2017 (Fig. 2a). The dominant PFTs within Europe include
254 croplands (20% mainly C3), grasslands (31% of which 24% are C3), and forests (25% of boreal forest, of which
255 16% are needleleaved evergreen and 9% are broadleaved summer-green, and 14% of temperate forest, of which
256 8% are broadleaved summer-green, 3% are needleleaved and 3% are broadleaved evergreen) (Fig.2b). The
257 spatial distribution of manure application on grasslands and croplands is shown in Fig.2c. Finally, Fig.2d
258 illustrates the actual river network derived from the HydroSHEDS DEM data (Lehner et al., 2008) and the one
259 corresponding to our river routing scheme at 0.5 degree resolution, highlighting that the representation of the
260 river network is not optimal due to the coarse spatial resolution of our model. This coarse resolution limits the
261 possibility of model validation to the downstream parts of larger river networks. Note further that the mouth of
262 the Rhine is more than 100 km too far east, which further limits model validation for that river.

263
264
265

Figure 2. Spatial distribution for each 0.5° grid cell of the continental European domain of (a) climate zones (according to the Köppen-Geiger classification); (b) dominant plant functional types (pft) (c) manure application

266 (in $\text{gC m}^{-2} \text{yr}^{-1}$); (d) the routing Network of ORCHILEAK (in blue). The real river network extracted from the
 267 European Environment Agency (<https://www.eea.europa.eu/legal/copyright>) is also shown.

268

269 The forcing data applied in our study are listed in table 1. They are the same as those used in Lauerwald et al.
 270 (2017) except for the meteorological forcing data and the land cover. The WFDEI meteorological forcing dataset
 271 used in this study was derived by applying the methodology originally used to create the WATCH Forcing Data
 272 (WFD) from the ERA-Interim reanalysis data (Weedon et al., 2014). The dataset has a 0.5° spatial resolution and
 273 a 3-hourly time step from 1978 to 2014. The land cover forcing data set, which gives the areal proportion of the
 274 13 PFTs within each 0.5° grid cell, was taken from Peng et al. (2017).

275

276

Table 1. List of the forcing files used for our simulations, along with their spatiotemporal resolution.

VARIABLE	SPATIAL RESOLUTION	TEMPORAL RESOLUTION	DATA SOURCE
Rainfall, snowfall, incoming shortwave and longwave radiation, air temperature, relative humidity and air pressure, wind speed.	0.5°	3 hours	WFDEI_GPCC (WATCH Forcing Data (WFD) by making use of the ERA-Interim reanalysis data, Global Precipitation Climatology Centre; Weedon et al. (2014))
Soil texture class	0.5°	-	Reynolds et al., 1999
Soil pH, soil bulk density, poor soil	0.5°	-	After HSWD v 1.1 (Fao et al., 2009)
Stream flow directions and topographic index	0.5°	-	STN-30p (Vörösmarty et al., 2000)
Floodplains and swamps	0.5°	-	Guimberteau et al., 2012
River surface area	0.5°	-	Lauerwald et al., 2015
10th, 50th, 90th percentile of the stream reservoir	1°	-	Derived from pre-runs with ORCHIDEE
Land cover	0.5°	-	Peng et al. (2017)

277

278 **Parametrization of hydrological processes.** ORCHILEAK was previously parametrized and validated for the
 279 Amazon (Lauerwald et al., 2017; Hastie et al., 2019; Lauerwald et al., 2020), Congo (Hastie et al., 2021) and
 280 Lena (Bowring et al., 2020) basins. In our study of the European river network, we used the default parameter
 281 values of Lauerwald et al. (2017) excepted for the surface roughness of the vegetation that was adjusted. This
 282 parameter increases the aerodynamic resistance near the surface when vegetation cover is low, leading to lower

283 ground temperatures and thus lower evaporation rates. This adjustment was deemed necessary in order to better
284 capture the observed mean and seasonal variability of the discharge along the European river network.

285 **Spin-up.** Before the model can be used to simulate C dynamics over the past decades, a spin up is needed to
286 reach an assumed steady state for the C fluxes during the pre-industrial period. This steady state is achieved by
287 spinning up ORCHILEAK for 15000 years. The spin up was realized by recursively looping over 27 years of
288 climate forcing using the WFDEI forcing dataset over the 1980-2006 period and constant land cover and
289 atmospheric CO₂ concentration of 286 ppm (Guimberteau et al., 2018) corresponding to year 1861. After the end
290 of the spin-up, the soil C stock across the entire European continent changed by less than 1% over a century of
291 simulation, which we considered close enough to steady-state.

292 **Transient runs.** Using the steady-state outputs as initial condition, the first part of the transient simulation
293 (1861-1977) was carried out with increasing atmospheric CO₂ concentration, changing land use and land cover
294 and with river routing activated while still looping over the same 27 years of climate forcing used for the spin-up
295 because no climate forcing data prior to 1978 was available. From then onwards, the WFDEI atmospheric
296 forcing data was applied over the entire period covered by this product (1978-2014).

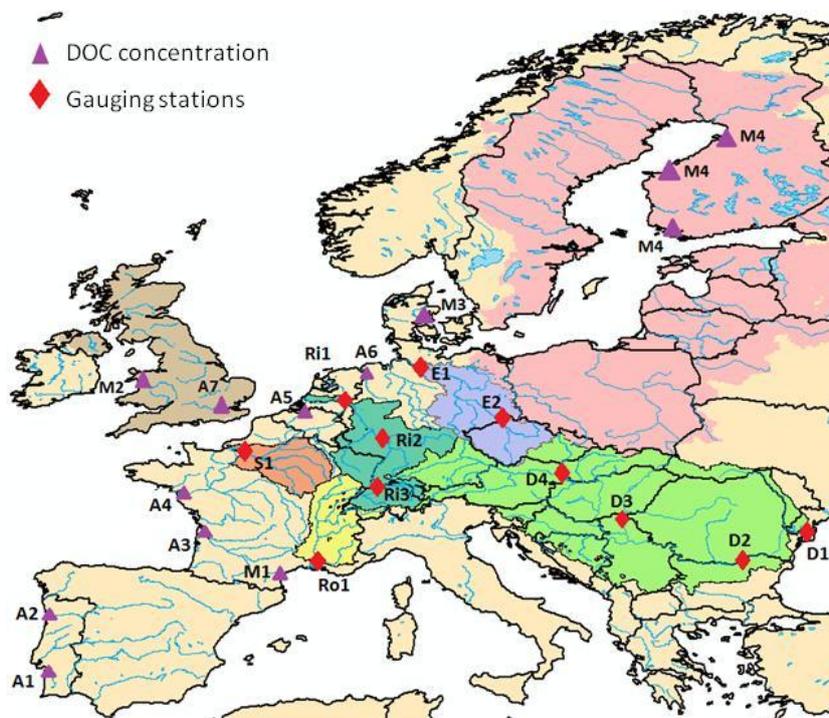

297

298 2.2.2 Model evaluation

299 Firstly, the simulated discharges were compared to times series of daily stream flow recorded at eleven gauging
300 stations from “The Global Runoff Data Center (GRDC), 56068 Koblenz, Germany” dataset. For comparison,
301 both observed and simulated discharges were aggregated at the monthly temporal resolution over the years 1980
302 to 2006. This period was chosen based on the GRDC data coverage. Model performance was then evaluated
303 with respect to several variables of the terrestrial C cycle. Firstly, simulated Net Primary Production (NPP) was
304 compared to two different data products. The first one, the CARbon DATA Model fraMework (CARDAMOM;
305 Bloom et al., 2015) built from model data fusion analysis at 1° resolution. The second one is the Global
306 Inventory Modeling and Mapping Studies (GIMMS) at 0.5° resolution based on AVHRR and MODIS sensors.
307 GIMMS uses several atmospheric forcing data set to derive NPP. Those are CRUNCEP version 4 P1 and P2
308 (Rainfall, cloudiness, relative humidity and temperature taken from the CRU (Climate Research Unit), while the
309 other fields such as air pressure, longwave radiation, wind speed are directly derived from NCEP (National
310 Center for Atmospheric Research)), ECMWF (European Centre for Medium-Range Weather Forecasts),
311 MERRA2 (the Modern-Era Retrospective analysis for Research and Applications, Version 2) and NCEPR2
312 (<https://www.esrl.noaa.gov/psd/>). For our comparison, we calculated the average of the NPP obtained with these
313 five atmospheric forcing files. The NPP values from ORCHILEAK and GIMMS were averaged over the period
314 1982-2006 while CARDAMOM only covers a shorter time period comprised between 2001 and 2010. Modeled
315 NPP was then compared to the NPP data products at the European scale and at the scale of five large European
316 basins for which we also evaluated the simulated river discharge and DOC fluxes, and which taken together,
317 represent 19 % of the model domain (Fig.3): the Danube, Rhine, Elbe, Rhone and Seine. All five basins are
318 located in an oceanic or humid continental climate (Fig.2a) although the Rhone basin extends further into the
319 Mediterranean climate zone. The basin characteristics according to land cover types are as follows: the Danube

320 and the Elbe basins have both a high proportion of croplands (around 40%), the remainder being mostly covered
321 by grasslands and boreal forests. The Rhone is covered by 50% of grasslands, while in the Seine basin croplands
322 reach 50%. The Rhine has a more diverse land cover with a substantial proportion (about 30%) of boreal (10 %)
323 and temperate (20 %) forests, 35% of grasslands and 25% of croplands. See table S2 for further details.

324
325 **Figure 3.** Map of continental Europe delineating the (group of) catchments of focus in this study and the location of
326 observed discharge and DOC concentrations. Catchments, from west to east are: All UK (light brown), Seine
327 (orange), Rhone (yellow), Rhine (dark green), Elbe (violet), All Baltic (pink) and Danube (light green). Observations
328 include GRDC stations (red diamonds) in the Seine (S1-Poses), Rhone (Ro1-Beaucaire), Rhine (Ri1-Lobith, Ri2-Main
329 in Frankfurt, Ri3-Basel), and Danube (D1-Ceatal Izmael, D2-Svistov, D3-Tisza in Senta, D4-Bratislava) catchments,
330 as well as river stations where DOC concentrations were measured (purple triangles): A1-Douro, A2-Sado, A3-
331 Gironde, A4-Loire, A5-Scheldt, A6-Ems, A7- Wales, A8-Thames, M1-Tech, M2-Wales, M3-Denmark, M4-Finland
332 (Abril et al 2002, Mattsson et al., 2008).

333
334 SOC from the Harmonized World Soil Database (HWSD) was used to evaluate the simulated SOC stocks
335 against observation-based products. HWSD is a global soil database framed within a Geographic Information
336 System (GIS) that contains up-to-date information on world soil properties. In particular, this dataset reports the
337 organic carbon content in the soil as well as the soil bulk density. The bulk density was calculated in two
338 different ways. The first one follows the method described in Saxton (1986) where the bulk density is related to
339 the soil texture, this approach tending to overestimate density in high porosity soils or in OC rich soils. The
340 second method uses the SOTWIS database in which the bulk density is calculated as a function of soil type and

341 depth. In this database, all variables are reported for the topsoil (0-30cm) and the sub-soil (30-100cm) horizons.
342 For comparison purposes, our simulated SOC stocks were thus integrated over the same depth intervals. We also
343 assessed briefly the extent to which our model can reproduce the main features in observed soil DOC profiles.
344 To that end, we compared our simulated DOC profile averaged over the entire European forest biome against the
345 one established by Camino et al. (2014) on the basis of a synthesis of local measurements. Unfortunately, similar
346 synthetic profiles based on observations have not been constructed for croplands and grasslands.
347 The key variables of interest in our study are the DOC leaching flux from the soil and the DOC export flux to the
348 coast. These fluxes require accurate simulation of the water discharge fed by runoff and drainage as well as of
349 DOC concentrations in the leaching flux and in the riverine flux. For the leaching flux, our simulation results
350 were compared to measured fluxes reported by Kindler et al. (2011) across different locations. Because the
351 observed DOC leaching fluxes reported by Kindler et al. (2011) are based on local measurements that are not
352 easily comparable to simulated fluxes at the coarse spatial resolution of our model (0.5° or about $2 \cdot 10^3$ km² at
353 the corresponding latitude), we nevertheless consider the comparison against measured river DOC fluxes more
354 relevant for our purpose, as rivers are good integrators of mean, larger-scale catchment properties. For the
355 riverine export fluxes, we assessed the modeled discharges and DOC concentrations separately. For evaluation
356 of stream DOC concentrations, DOC data were extracted from the GLObal RIVER CHEMISTRY database
357 (GLORICH, Hartmann et al., 2014) for the Rhine and Elbe basins and from the “Eau de France” database for the
358 Seine and Rhone basins. These data were complemented by river DOC concentrations reported by Abril et al.
359 (2002) for 9 river mouths (Sado, Thames, Ems, Scheldt, Gironde, Douro, Loire, Elbe and Rhine), and by
360 Mattsson et al. (2008) for several river basins located in Finland, Denmark, Wales and France.

361

362 **3 Results and discussion**

363 **3.1 Model evaluation at pan-European and catchment scales**

364 **3.1.1 Discharge**

365 Figure 4 compares the simulated discharge against observations for selected stream gauging stations (section 2).
366 Those stations are located near the mouth of large rivers (Danube, Rhine, Rhone, Elbe and Seine) but also
367 include a few locations further upstream the same rivers or at major tributaries (Fig.3). The comparison is
368 performed for the period 1990-2000, except for the Rhone at Beaucaire and the Danube at Svistov for which the
369 observed stream gauge data cover only a shorter period. Overall, the model reproduces the observations well,
370 both in terms of amplitude and seasonality, except for the Elbe at Neu Darchau for which the temporal variability
371 is well captured but the absolute discharge is overestimated.

372 Note that the simulated catchment area often diverges (by -25% to +30 %) from the observed value due to the
373 coarse resolution ($0.5^\circ \times 0.5^\circ$) of ORCHILEAK (Table S3). As a result of the model resolution, smaller tributaries
374 are not represented individually and each grid cell was fully assigned to one larger river basin. The effect of the
375 resolution is also shown in Fig.2d which compared the observed and modeled river network. Discrepancies
376 between model and real world catchment area will translate into proportional biases in discharge simulation.

377 Furthermore the 0.5° resolution is too coarse to be able to represent perfectly the pathways of the river. Our
378 model tends more often to underestimate the catchment area, while its yearly mean discharge is overestimated,
379 except at the Beaucaire station along the Rhone River. The bias can be significant and cannot be explained by
380 the model resolution alone.

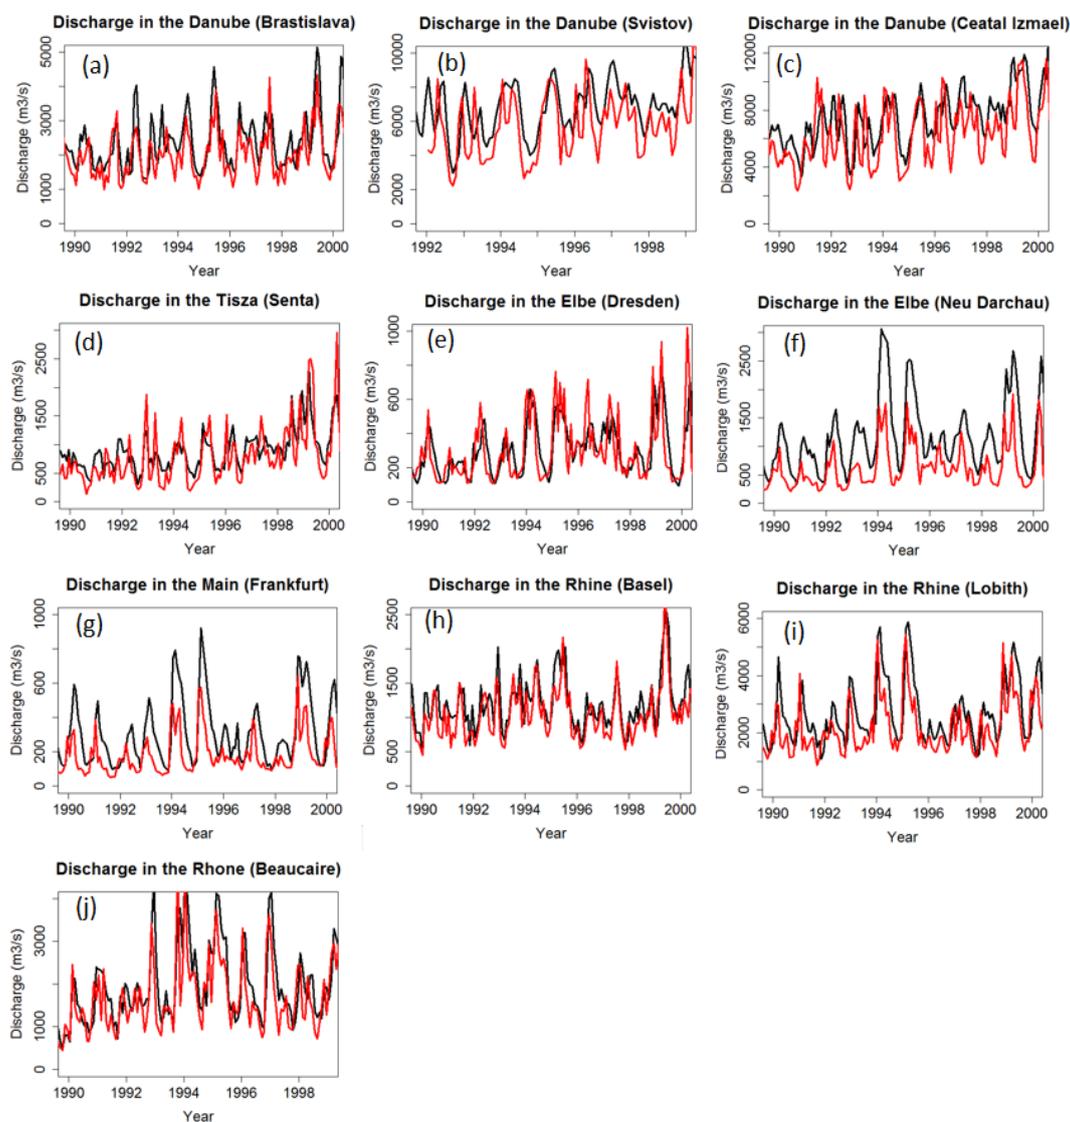

Figure 4. Modeled (black) and observed (red) time series of discharge at the GRDC gauging stations in the Danube (a-c) and its tributaries (d), Elbe (e-f), Rhine and its tributaries (g-i) and Rhone (j). Note the different time periods of measurements. See figure 3 for exact location.

385

To evaluate model performance for discharge, we used the Pearson's coefficient of determination (R^2) and the Nash Sutcliffe modeling efficiency (NSE, Nash and Sutcliffe (1970)). The R^2 only accounts for the correlation with regard to the temporal variability. With R^2 values comprised between 0.43 and 0.62 for all stations, we conclude that the observed seasonality of the discharge along large European rivers is reasonably well reproduced by the model. The NSE not only accounts for the correlation between observed and simulated temporal signals, but also for the model's ability to reproduce absolute discharges. The statistics confirm our previous observation that the model generally overestimates discharges (low NSEs) except for stations Elbe in Dresden, Rhone in Beaucaire, Rhine in Basel and Danube in Bratislava where both the mean and temporality are well captured. Two stations have negative NSE values, which means that the error variance estimated by the model is significantly larger than the variance of the observations; in others words, the difference between model and observations is significant. The mean error (%), that is the weighted difference between the average from the model and the one from observation, confirms that low NSEs are mostly due to overestimated discharges, which is further demonstrated by high mean errors. More results for other European catchments can be found in table S3.

3.1.2 NPP, biomass and soil organic C stocks

We briefly compare simulated NPP with the gridded observation-based products GIMMS and CARDAMON (section 2.2.2) as C fixation by the vegetation exerts an important control on DOC stocks in the soil and thus on DOC leaching. We first perform our comparison over a large domain comprised between -10° and 30° in longitude east and 35° and 70° in latitude north - covering the area from Ireland to the Western Black Sea (where the Danube flows into) and from the south of Spain to the north of Scandinavia. Over this area (referred to as "Europe" from here onwards), the modeled yearly averaged NPP amounts to $445 \text{ gC m}^{-2} \text{ yr}^{-1}$, a value in remarkable agreement with both GIMMS and CARDAMOM estimates of $430 \text{ gC m}^{-2} \text{ yr}^{-1}$ and $460 \text{ gC m}^{-2} \text{ yr}^{-1}$, respectively. Those two datasets are entailed with an uncertainty that we assume similar to that reported for the MODIS dataset, i.e. 20% (Turner et al 2006). The total living biomass in Europe is simulated at 15.5 PgC or 2.3 kgC m^{-2} . This value is in good agreement with the recent estimate by Avitabile and Camia 2018, which report a biomass stock at around 16 PgC. We estimate that the total soil carbon stock amounts to 58 PgC. Averaged over the first meter of the soil horizon, this corresponds to a value of 9.5 kgC m^{-2} which is comparable to that of HWSD (6 kgC m^{-2}) when using the SOTWIS method to compute the bulk density, but significantly lower when applying Saxton's method (22 kgC m^{-2}), plausibly because the latter overestimates the bulk density in OC-rich soils (Kochy et al., 2015).

Table 2 summarizes the yearly average NPP at the scale of the five selected European catchments. Simulated NPP is of the same order of magnitude as both observation based datasets, without any systematic bias towards an underestimation or overestimation. To provide error bounds for the observational products, we calculated the average standard deviation between yearly-mean values. For GIMMS, we also included the standard deviation induced by the use of the five distinct meteorological forcing files to assess the NPP (section 2.2.1). We find that our simulated catchment averaged NPP fall within the error bounds of the observational products for the Rhine and the Rhone while for the Danube, Elbe and Seine, simulated NPP is slightly above the upper error range.

Table 2 reports the biomass and soil carbon (SOC) stocks for the 5 river basins. SOC stocks are usually slightly overestimated compared to HWSD. Results have also been aggregated at the intermediate scale of broad climate zones to analyze how well our model performs for distinct climate regimes. Again the method to calculate the bulk density (section 2.2.2) leads to large uncertainties in observed SOC stocks. Nevertheless, we find that simulated SOC stocks for the warmer climates (Semi-arid and Mediterranean) match well the SOC stocks of the HWSD. However, for other regions, we systematically underestimate the SOC stock compared to HWSD using the Saxton Method, especially in the subarctic climate, but we are closer to the observed values relying on the SOTWIS method for the bulk density. This result is expected since the model does not represent peatlands, which contain important quantities of SOC (Leifeld and Menichetti 2018).

430 **Table 2 Comparison of modeled NPP (1982-2006) against estimates from the CARDAMOM (2001-2010) and GIMMS (1982-2006)**
datasets. The mean of the two datasets, along with an assessment of the uncertainty (based on MODIS) and of the standard
deviation are also reported. In addition, the modeled biomass stock and soil organic carbon (SOC) content (first 1m) are compared
with values reported in the HWSO database, using two methods (Saxton and SOTWIS) to calculate the soil bulk density. All
variables and processes are reported for the large-scale basins of focus in this study (see fig. 3 for location), the main climate zones
of continental Europe and the whole model domain.

3.1.3 Soil DOC stocks

Comparison between observed and modeled DOC stocks and fluxes is more difficult than for biomass and SOC because those have not been assessed at large spatial scales. Nevertheless, representative soil DOC concentration profiles for coniferous and broadleaved forests of Europe have been compiled by Camino et al. (2014). These profiles were used to evaluate our model. Overall, we found that ORCHLEAK slightly overestimates DOC concentrations, especially in the very topsoil horizons with modeled values around 100 mg l^{-1} against $40\text{-}60 \text{ mg l}^{-1}$ in the observations (Fig. 5). We also simulated higher concentrations in broadleaved forests than in coniferous forests while Camino et al. (2014) obtained the opposite.

When integrated over the first meter of the soil horizon of forested ecosystems (28 % of the surface area), the modeled and observed DOC stocks amount to 22.2 and 11.3 gC m^{-2} , respectively. The underestimation of SOC stocks combined with a likely overestimation of DOC stocks suggests that SOC decomposition rates in the new soil carbon module may be slightly too high. It is however difficult to generalize this conclusion because of the lack of synthesis data for other land cover types, especially croplands and grasslands which together represent about 50 % of the total European land area. Modeled DOC stocks averaged over broad climate regions reveal highest values for the oceanic climate with 32 gC m^{-2} and the Mediterranean climate with 26 gC m^{-2} . Semi-arid and humid continental climates have similar concentrations of respectively 17.5 and 20 gC m^{-2} and it is in the coldest climates (subarctic and tundra) that we find the lowest DOC concentrations around 8 gC m^{-2} .

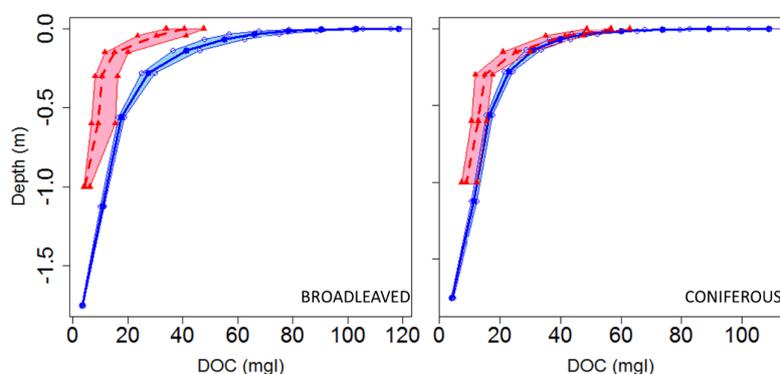

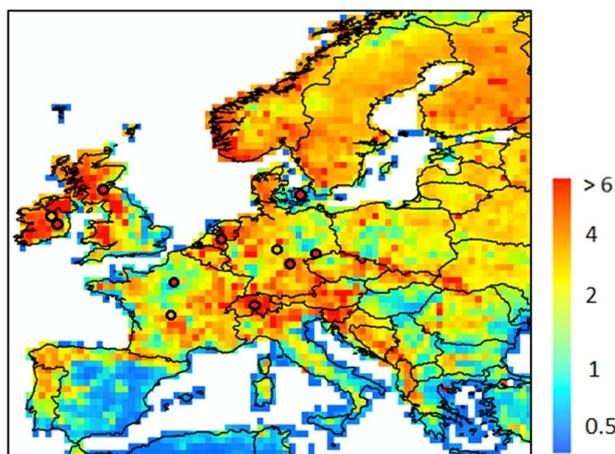

Figure 5. Modelled (blue) versus observed (red dashed) DOC concentration profiles averaged over the soils of the European Coniferous and Broadleaved forest biome. Data from Camino et al. (2014). The shaded area represents the 95% bootstrap confidence interval for model and observations.

3.1.4 DOC leaching fluxes

The model simulates a yearly-mean DOC leaching flux over Europe of $14.3 (\pm 10) \text{ TgC yr}^{-1}$ (Fig 6), the standard deviation being here coarsely approximated by spatial variability. The average area specific flux rates is of $2.6 (\pm 2.5) \text{ gC m}^{-2} \text{ yr}^{-1}$. We compared DOC leaching fluxes with site level observations from Kindler et al. 2011, across 17 local measurements, each sampled fortnightly during the period October 2006 until March 2008. Our modeled average of $2.6 (\pm 2.5) \text{ gC m}^{-2} \text{ yr}^{-1}$ is of the same order of magnitude as the observed one ($4.2 \text{ gC m}^{-2} \text{ yr}^{-1}$). Although the modeled mean is about 38 % lower than the one measured, the standard deviation representing the spatial variability in simulated DOC leaching fluxes over all our model grid cells encapsulate the observational mean, highlighting a significant heterogeneity that is difficult to embrace with local measurements alone.

470 **Figure 6. Modelled yearly mean terrestrial DOC leaching flux (period 1979-2006) to the river European river network (in $\text{gC m}^{-2} \text{yr}^{-1}$). The local observations from Kindler et al., 2010 are also reported, using the same scale. Note that the local observations cover a much shorter time period and may not be representative of the whole year.**

The seasonal distribution of the DOC leaching flux is shown in Fig. 7. On average, the leaching flux per season averaged over Europe amounts to 1.6, 1.3, 0.5 and 1.4 TgC month^{-1} in winter, spring, summer and autumn, respectively. If we exclude
475 the high latitude and high altitude regions (Scandinavia, the Alps), a clear seasonality is observed with the lowest fluxes in summer and spring and highest fluxes in winter and autumn. In the high latitude/altitude regions, the pattern is different with highest fluxes in spring which extends to the summer in the Alps, and corresponds to the snowmelt period. The highest fluxes per unit area are simulated in Scandinavia during the spring season, even though peatlands are not represented in the model. Some regions are leaching hotspots such as the Alps throughout the year, the West Balkans during autumn and the
480 Western flank of the UK in autumn and winter. This is mainly due to the high local runoffs and thus runoff rates in these regions.

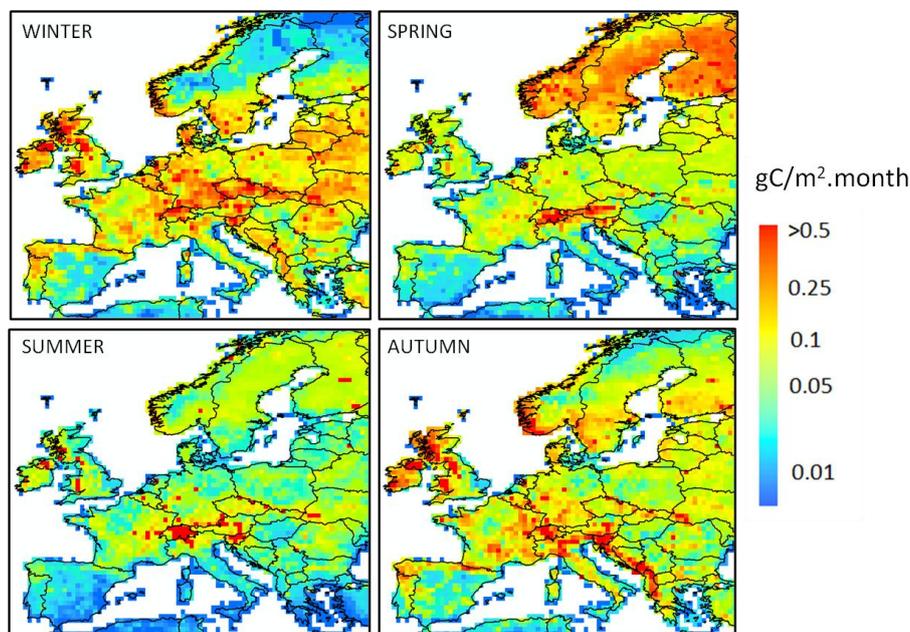

Figure 7. Seasonal distribution of the terrestrial DOC leaching flux ($\text{gC m}^{-2} \text{ month}^{-1}$), average over the period 1979-2006. A logarithmic scale is used to better highlight the spatiotemporal gradients.

485

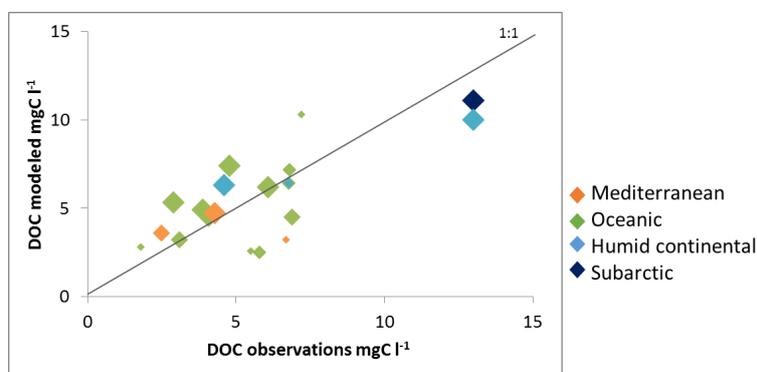

3.1.5 Fluvial DOC decomposition and export fluxes

The export of DOC from the European river network to the coast is arguably the best monitored variable against which our model can be evaluated. Using this flux to build confidence in our estimate of the terrestrial DOC leaching requires an assessment of the DOC degradation within rivers, a process that is controlled by the hydrology and the half-lives of reactive
490 DOC compounds. In the model, the first-order decomposition rates at a given temperature of 28°C are equal to 0.3 d^{-1} and 0.01 d^{-1} for the labile and refractory DOC pools, respectively. Based on those values and the simulated distribution of labile and refractory DOC, the estimated bulk decomposition rate constant averaged over the entire model domain is equal to 0.05 d^{-1} , which corresponds to a half-life for DOC of about 14 days (Table 3). This rate constant varies across Europe but always remains within the same order of magnitude, with half-lives ranging from 6 to 20 days ($0.035\text{-}0.122 \text{ d}^{-1}$). These
495 decomposition rates are in good agreement with the average rate reported by Berggren and Al-Kharusi. (2020) of 0.037 d^{-1} based on field experiments carried out at multiple river sampling locations across Europe. We thus conclude that DOC decomposition rates used in ORCHILEAK are reasonable, and fluvial DOC fluxes are a valid proxy to evaluate simulated DOC leaching fluxes.

500 **Table 3. Estimated river DOC decay rates applied in ORCHILEAK. Values are reported for four large river catchments and for the six dominant climate zones**

	REGIONS	DECAY RATES (day ⁻¹)
BASIN	Rhine	0.074
	Danube	0.043
	Meuse	0.056
	Rhône	0.072
CLIMATE ZONE	Semi-arid	0.035
	Mediterranean	0.046
	Oceanic	0.053
	Humid continental	0.048
	Subarctic	0.064
	Tundra	0.122

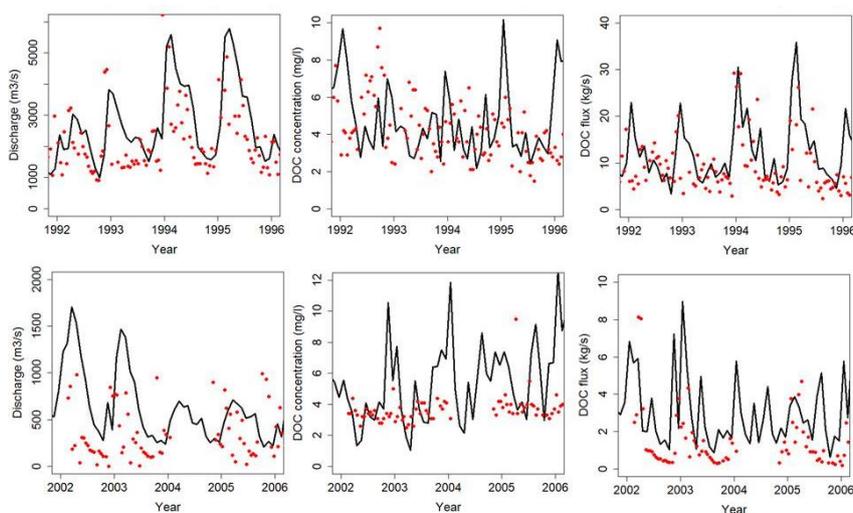

505 **Figure 8. Modelled river DOC concentration against observed values. The color code indicates the dominant climate zone for each catchment while the size of the diamond is proportional to the catchment area according to the following classes: < 10 000 km², < 50 000 km², < 100 000km² and > 100 000 km². See table S4 for further details.**

Figure 8 compares modeled versus observed multi-annual mean DOC concentration at specific locations or within a group of small river catchments. Local DOC measurements include data near the mouth of the Rhine, Elbe, Rhône and Seine rivers (discharge, DOC concentration and fluxes for the Rhine and Seine in figure 9). In addition, Abril et al. (2002) report DOC concentrations measured at nine river mouths discharging along the Atlantic façade and the North Sea, three of which (Rhine (NL), Scheldt (BE) and Gironde (F)) resolve the seasonality while the other six (Elbe (GE), Ems (GE), Thames (UK), Loire (FR), Sado (P), Douro (P)) only rely on a single measurement per year. Both GLORICH and Abril et al. (2002) report DOC concentrations at the mouth of the Rhine and the Elbe but their values diverge because in addition to analytical uncertainties, the sampling period and data density are not the same. Measured values are equal to 4.3 and 2.9 mg C l⁻¹ for the Rhine and 4.6 and 6.1 mg C l⁻¹ for the Elbe, respectively highlighting inherent variability in observational data. To complement these local samplings, we also compared our simulated DOC concentrations with those of Mattson et al. (2008) for several groups of catchments in Finland (9 spread over the whole country), Denmark (10 draining into Horsens fjord), the UK (10 draining into the River Conwy) and France (5 draining into the River Tech). All measured DOC concentrations ranged from 2.5 mg C

520 l^{-1} to $10 \text{ mg C } l^{-1}$ except in two regions in the north (Finland and basins flowing into the Baltic sea) where concentrations exceeded $10 \text{ mg C } l^{-1}$. For most of the data, the model slightly overestimated the river DOC concentrations. The model results also suggest that the concentrations broadly increase with latitude, with the higher values found in humid continental and subarctic climate and the lower ones in the Mediterranean climate, a result in agreement with the observations from Mattson et al. (2008). Such pattern possibly results from decreasing mean annual air temperature and runoff in Northern Europe that favor incomplete decomposition of litter and DOC, thus favouring DOC production, while at the same time DOC turnover rates in the soils are decreased. Also the increased abundance of forests, and in particular coniferous forests, is a valid explanation for higher DOC leaching (Lauerwald et al. 2012). However, it is important to keep in mind that we're missing the peatlands, suggesting that we could lack part of the DOC leaching in subarctic and tundra regions leading to even higher DOC fluxes further in the North. Finally, the comparison reveals that model performance tends to improve with catchment size, likely reflecting the difficulty to capture the DOC dynamics at the small scale with the current resolution of ORCHILEAK. But overall, our model is capable of reproducing observed yearly mean DOC concentrations for a wide range of river basins spread between Finland and Portugal.

535 **Figure 9.** Time series of discharge (left), DOC concentration (middle) and DOC fluxes (right) in the river Rhine at Lobith (top row, period 1992-96) and in the Seine at Poses (bottom row, period 2002-2006. See figure 3 for location of stations.

The temporal evolution of observed river DOC fluxes is only available at four stations (Rhine, Elbe, Rhône and Seine) where DOC time series have been recorded over multi-annual periods (Fig. 9). The multi-year mean modeled DOC fluxes are estimated for the Rhine, Elbe, Rhone and Seine at 11.9 , 7.2 , 8.8 and 3.2 kg s^{-1} , respectively. The observations amount respectively to 7.9 , 3.6 , 4.6 , 1.6 kg s^{-1} . For all stations, the model thus overestimates slightly fluvial DOC fluxes, which is not surprising since the model tends to overestimate the discharge. At these four stations, ORCHILEAK also slightly overestimates river DOC concentrations except for the Seine where concentrations are largely underestimated and discharge largely overestimated. In terms of temporal correlation, the simulated DOC flux for the Rhone compared to the observed one yields a R^2 of 0.6 and a mean error of 92% (results for the Seine, Elbe and Rhine are reported in supplementary table S5). In figure 8, we clearly see a large overestimation of the temporal variability in DOC concentrations and this could lead to an overestimation in DOC fluxes since there is a positive relationship between concentrations and discharge. The overestimation of DOC concentrations and consequently of DOC fluxes could be due to high DOC leaching.

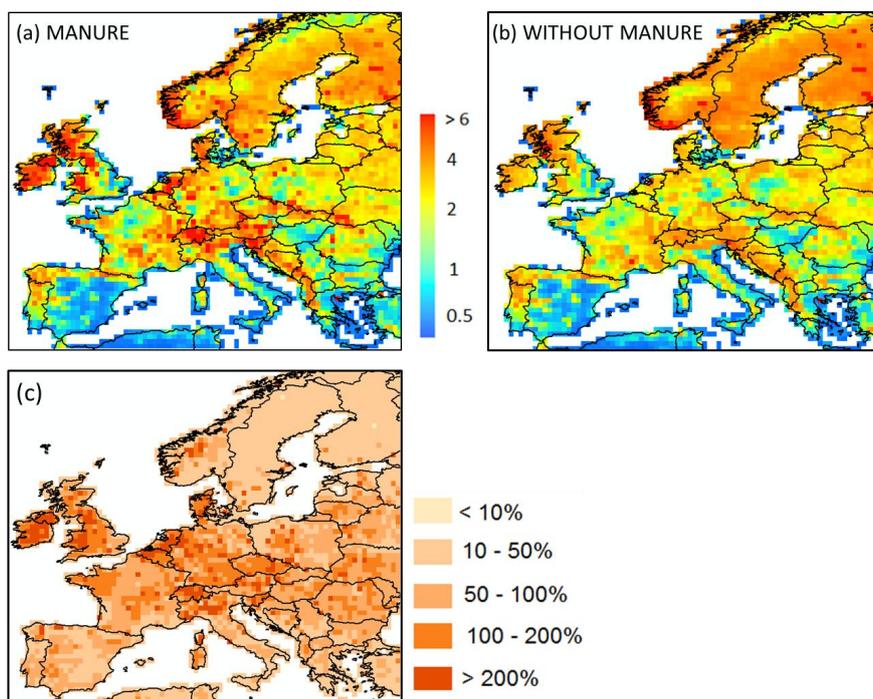

The overestimation of DOC fluxes can also be due to the fact we choose to not recalibrate the hydrology scheme but instead we optimized the model for the discharge by adjusting the surface roughness of the vegetation (section 2.2.1). Since those four stations are all located in the same region with the same type of land cover (Western Europe), two other locations have been selected: England and the Baltic Sea. For those two locations, there are no time series data for DOC flux but some studies have measured DOC concentrations/fluxes. Worrall et al. (2012) estimated DOC concentration across UK and Fransner et al. (2016) reported modelled DOC concentrations for all the catchments flowing into the Baltic Sea.

Finally, although the model-data comparison points to a slight overestimation of the river DOC export flux, our pan-European estimate amounts to 12.3 TgC yr^{-1} . This estimate is in fact about 35 % lower than the one reported in another model study by Li et al. (2019), based on the TRIPLE-HYDRA, a process-based model for which the DOC export flux reaches 19.3 TgC yr^{-1} . Li et al. (2019) applied the model at the global scale and simulation results were primarily evaluated against observations in the world-largest rivers and for Europe only included the Volga River. Li et al. (2019) then applied the model for multiple rivers in Europe such as the Danube, the Po, and the Elbe. Despite these different scales of analysis, the export fluxes predicted by both models fall within the same order of magnitude.

3.1.6 Manure implementation

The implementation of manure significantly affects DOC leaching from grasslands and croplands (Fig. 10) which cover more than half of the studied region. The average annual input rate of manure into the soil is around $2.5 \text{ gC m}^{-2} \text{ yr}^{-1}$ (Fig. 2c). With manure implementation, the DOC leaching rate increase drastically (average of +72% compared to the DOC leaching without manure), in particular in the oceanic and humid continental climate regions, where the average DOC leaching rate changes from 1.6 to $2.7 \text{ gC m}^{-2} \text{ yr}^{-1}$ and 1.7 to $2.5 \text{ gC m}^{-2} \text{ yr}^{-1}$, respectively. In whole Europe, manure implementation leads to an increase of total DOC leaching into the river network from 9.8 to 14.3 TgC yr^{-1} .

570

Figure 10. Comparison of modeled yearly mean terrestrial DOC leaching flux (period 1979-2006) to the river European river network (in $\text{gC m}^{-2} \text{ yr}^{-1}$), with (a) and without the manure (b). (c) Increase of DOC leaching in percentage compared to DOC leaching without the manure implementation.

3.2 European-scale DOC leaching dynamics

575 3.2.1 Drivers of DOC leaching

Here, we analyze what controls the spatial distribution and temporal variability in the DOC leaching. Figure 11 shows seasonal variability of DOC leaching and total runoff (surface runoff plus drainage) in different climate zones of Europe, revealing a clear and consistent relationship between those two fluxes. The seasonal peak in DOC leaching consistently occurs in winter while minimum values are found during summer. These results suggest that both spatial and temporal variability in leaching are correlated to total runoff.

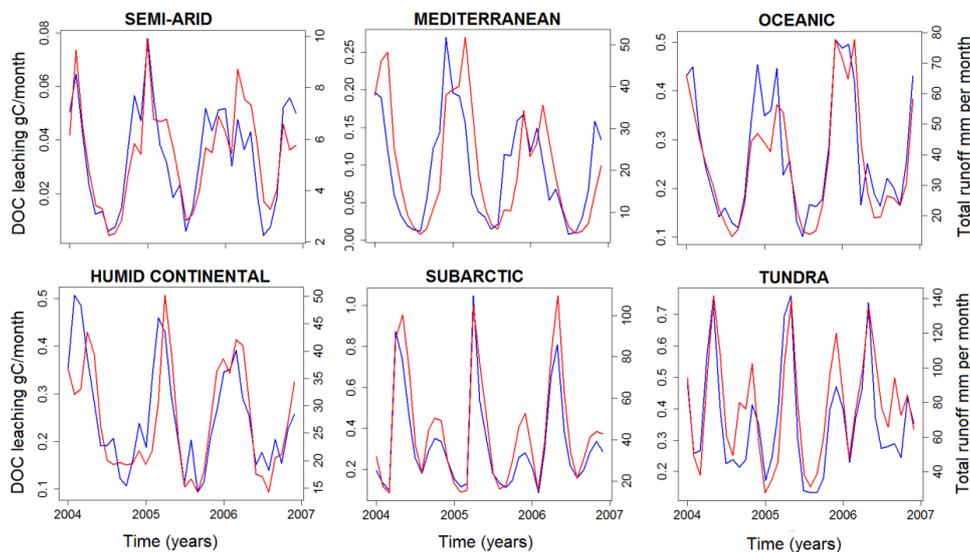

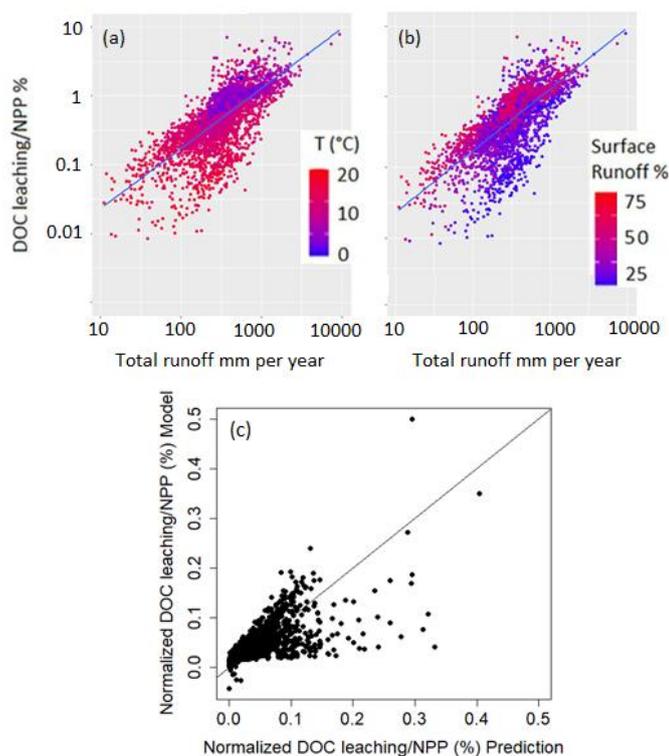

Figure 11. Simulated DOC leaching flux ($\text{gC m}^{-2} \text{month}^{-1}$) (blue) and total Runoff (mm per month) (red) for the six largest climate zones (period 2004-2007).

585 To further explore the environmental controls the DOC leaching, we expressed DOC leaching as fraction of terrestrial NPP (Figure 12). Doing this, we assume that NPP, which is undoubtedly the first source for DOC production, is as well an important control of the DOC leaching flux. Moreover, normalizing DOC leaching by NPP, we strive to show the possible influence of other controls, allowing for a more in-depth analysis of the effect of hydrology and climate on the DOC leaching flux. Figure 12 reveals that the fraction of terrestrial NPP lost to DOC leaching increases, as expected, with total runoff. Moreover, this fraction increases with the contribution of surface runoff to total water loss from surface runoff plus drainage (Fig. 12b). This can be explained by the general decrease in soil DOC concentrations with depth (Fig. 5), leading to higher DOC concentrations in surface runoff than in drainage. In fact, according to our simulations, 97% of the leached DOC is concentrated in the surface runoff. Note that higher total runoff is often associated with a higher contribution of surface runoff, which leads to a ‘flushing effect’ where high runoff events contribute a disproportionate high fraction of the long-term DOC leaching (Idir et al. 1999, Raymond and Saiers 2010). Finally, we found higher leaching to NPP ratios at lower temperatures (Fig. 12a), hinting at the fact that lower temperatures lead to longer turnover times of DOC in the soil, and thus higher concentrations in the leaching flux (section 2.1.2).

600 **Figure 12.** Fraction (%) of terrestrial NPP that is leached as DOC in the river network as a function of total runoff. Each point
 represents the grid-cell average of both metrics for the entire simulation period (1979-2006). In panel (a) the color scale represents
 the grid-cell average temperature (°C) while in panel (b), the color scale represents the ratio of surface runoff to total runoff in
 percentage. Panel (c) the normalized predicted DOC leaching flux to NPP ratio (equation 13) against the normalized simulated
 values.

605

To better quantify the effects of all these drivers on DOC leaching, we fitted a multi-linear regression model to predict the
 ratio of DOC leaching to NPP as a function of surface runoff, drainage and temperature at all grid points and for each month
 over the simulation period (eq. 13). To compare the importance of each predictor for the spatiotemporal patterns of DOC
 leaching, we normalized all variables V_i of equation 13 according to equation 14 (where i is the cell index).

$$\frac{DOC\ leaching}{NPP} = K_0 + K_R * Runoff + K_D * Drainage + K_T * e^{T(^{\circ}C)} \quad (13)$$

$$K_0 = 0.01 \pm 7 * 10^{-4}$$

$$K_R = 0.342 \pm 0.009$$

$$K_D = 0.276 \pm 0.014$$

$$K_T = -0.055 \pm 0.013$$

610

(p-value < $2 * 10^{-16}$ except for temperature where p-value = $2.7 * 10^{-5}$)

$$V_{i,N} = \frac{V_i - V_{min}}{V_{max} - V_{min}} \quad (14)$$

To rule out any significant multi-collinearity in the regression model, we calculated for each predictor the Variance Inflation
 Factor (VIF). The VIF evaluates the correlations among all predictors which could impact the robustness of the regression
 model (James et al., 2017). The closer the VIF is to 1, the more robust is the model. In our regression, VIF's of the runoff,

drainage and temperature are respectively 1.13, 1.13 and 1.01, confirming that our prediction is robust and not biased by high multicollinearity.

In Fig. 12 (c), the DOC leaching simulated by ORCHILEAK is compared with the one predicted by equation 13. Our simple regression model is able to reproduce the simulations with a residual standard error of 0.68% and a R^2 of 0.45. The coefficients of our regression model reveal that spatio-temporal variability in DOC leaching is mainly driven by the surface runoff (K_R) and drainage (K_D). Air temperature as third control of DOC leaching is of subordinate importance as reflected by its low predictor's coefficient (K_T).

Table 4 summarizes for each climate zone in Europe the DOC leaching fluxes, in total numbers and normalized by NPP, as well as other important components of the terrestrial C budget. Since runoff and temperature were identified as the controlling factors of the DOC leaching flux, normalized DOC leaching fluxes are expected to be significantly different among climate zones. Indeed, the fraction of NPP lost to the river network as DOC is the lowest in the semi-arid region (0.13%) where annual precipitation is low (total runoff around 92 mm per year) and temperatures are high.

Table 4. Key physical and biogeochemical characteristics of the six dominant climate zones of the European domain.

Variables	Unit	Semi-arid	Mediterranean	Oceanic	Humid continental	Subarctic	Tundra
Area	km ²	3.01E+11	8.74E+11	1.38E+12	2.11E+12	9.03E+11	1.56E+11
Leaching	gC m ⁻² yr ⁻¹	0.35	1.01	2.73	2.5	2.84	4.2
NPP		264.1	389.9	561.3	526.4	338.3	344.2
HR		175.5	278.6	390.6	345.7	255.3	266.9
Harvest (crop)		74.7	68	111.8	112.6	15.7	30.5
Harvest (wood)		5.4	25	46.1	40.7	41	41.8
LUC		-0.04	-4.8	-5.3	-7.7	-15.9	-3.7
NEE calculated		87	107.5	160	175	82.1	73.7
Leaching/NPP	%	0.13	0.26	0.49	0.48	0.84	1.22
Leaching/NEE		0.4	0.94	1.71	1.43	3.46	5.7
Runoff	Mm yr ⁻¹	30	63	82	91	236	404
Drainage		62	229	406	236	290	517
Temperature	°C	15	14.6	10.4	7.8	1.8	4.6

630 The highest fraction of NPP exported to rivers as DOC is found in the tundra climate and reach 1.22%. That can be explained by high runoff and drainage (reaching 920 mm per year) in this climate zone, but also by low temperatures lowering the fraction of DOC already decomposed within the soil column. The subarctic climate also presents a similarly high DOC leaching to NPP ratio with a value of 0.84%. The Mediterranean, Oceanic and humid continental climate zones present intermediate DOC leaching to NPP ratios of respectively 0.26%, 0.48% and 0.49%. Averaged over the whole of the EU-27, the DOC leaching flux normalized to the NPP amounts to 0.60 %.

3.2.2 Comparison with previous assessments of DOC leaching

In one of the first studies on the terrestrial C budget of Europe (Janssens et al., 2003) an imbalance (missing sink) between atmospheric CO₂ inversions and bottom up C stock change accounting was partly attributed to the loss of carbon from land to rivers in the form of DOC of around 4 gC m⁻² yr⁻¹. Our results, 2.6 ± 2.5 gC m⁻² yr⁻¹, support this hypothesis although we suggest a DOC leaching rate slightly lower than this early study. Our lower value may come from the fact that we did not simulate peatlands and organic soils which are known hotspots of DOC leaching (Leifeld and Menichetti 2018), in particular in areas such as the northern UK and Scandinavia. In terms of temporal variability, we found the highest DOC leaching in winter averaged over the continent (8.9 TgC in total for the six months of winter October to March) and the lowest in summer (5.4 TgC over the period April to September), consistent with the findings of Kindler et al. (2011). In terms of drivers of the DOC leaching fluxes, our results are in line with empirical findings by Gielen et al. (2011) that identified hydrology as the main driver of the inter- and intra-annual variability in DOC leaching. Similar conclusions have also been drawn by other empirical studies (Michalzik et al., 2001, Neff and Asner 2001, Worrall and Burt 2007).

It is also interesting to compare our results with recent global and regional model studies of DOC leaching in tropical and boreal ecosystems. For the Amazon and Congo basins, Hastie et al. (2019, 2021) found that 12 and 4 % of the NPP is exported each year to inland waters in the form of DOC, respectively – much higher than the one we report for Europe as a whole (0.6%). Note that for these tropical lowland river basins extensive riparian wetlands are an important source of DOC, which are of lower importance in Europe. For the Lena river basin located in the boreal region, Bowring et al. (2020) found a DOC leaching of NPP ratio of about 1.5%. In our model assessment, this ratio reaches a very similar value of 1.2% for the boreal portion of Europe. For the temperate zone, a ratio of 0.35% for the East Coast of the US can be calculated when dividing the average DOC leaching flux of 2.7 gC m⁻² yr⁻¹ simulated by Tian et al., 2015 by the average NPP of 780 gC m⁻² yr⁻¹ estimated by Zhao et al., (2005). Further, our value is quite similar to the one extracted from the global study by Nakhavali et al. (2020) that amounts to 0.5 % for the European domain only. Overall, this comparison highlights that in Europe, the fraction of NPP lost as DOC to the river network is significantly smaller than in other regions of the world. The lower value is likely due to the lower connectivity between terrestrial and aquatic systems due to the lack of extensive wetlands, which have been reduced by major regulation of the European river network.

3.2.3 Implications for the terrestrial carbon budget of Europe

The terrestrial carbon budget is controlled by NPP, heterotrophic respiration, crop and wood harvesting and land use change. Here we look at the net ecosystem exchange (NEE) which is the net C exchange between land and atmosphere (Kramer et al., 2002). However, this view neglects the leakiness of terrestrial ecosystems that permanently removes a fraction of the land C and export it to the river network. Moreover, we can argue that DOC leaching represents a fraction of NEE, while the remainder of NEE can be attributed to harvest, land use change and changes in biomass and soil C stocks. From 1979 to 2012, the average NEE in Europe is 860 TgC yr⁻¹ (123 gC m⁻² yr⁻¹), equaling about 28% of the total NPP (Fig. 13b). The ratio of DOC leaching to NEE shows drastic spatial variation, varying from an average value of 0.4% in the semi-arid regions to a value of 5.7% in the tundra. In whole Europe, the DOC leaching is about 3% of the NEE.

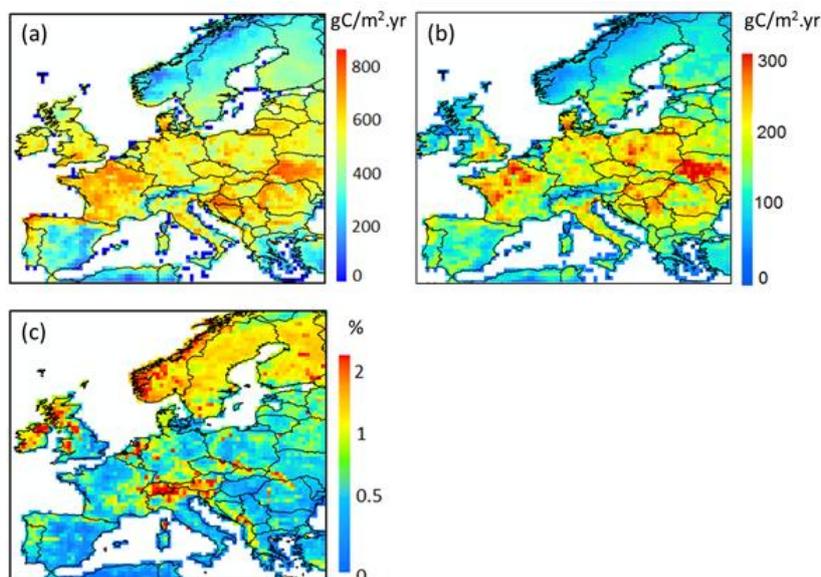

Figure 13. Grid-cell average (a) Net Primary Production, (b) Net Ecosystem Exchange and (c) fraction of NPP leached to the river network as DOC (%) for the period 1979-2006

675 4 Conclusion

We reconstructed the terrestrial and riverine C fluxes in Europe during period 1979-2012 using the ORCHILEAK LSM. The total C leaching from soil to European rivers is 14.3 TgC yr^{-1} on average, about 0.6 % of the estimated NPP and 3% of the terrestrial net up-take of atmospheric C. This flux shows large spatial and temporal variations. In specific, DOC leaching overall increases from warm and dry regions to cold and wet regions. However, since the model does not represent peatlands yet, the simulation results for subarctic and tundra regions in northern Europe could be biased. In whole Europe, DOC leaching rate is the highest in winter and lowest during the summer, mainly controlled by the seasonal variation of runoff. The implementation of manure lead to a significant increase in DOC leaching over the oceanic and humid continental region where croplands and grasslands are dominant. Our results contribute to a better assessment of the land-ocean C fluxes in Europe and to a better understanding of the effects of lateral C transfer on the terrestrial C budget. Combined with recent large-scale studies in tropical and boreal biomes as well as along the east coast of the US, an emergent view regarding the global role of DOC leaching on the terrestrial C balance and its underlying drivers is progressively emerging.

Code and data availability

The model code used in this study is available at DOI : 10.14768/75AC2F47-4691-46AF-9B12-B1A9629CBC56

690 All forcing data set are listed in table 1. Data of observed discharge used in this study are available from the Global Runoff Data Center (GRDC) at www.bafg.de/GRDC. Data of observed DOC concentrations in France are provided by eau de France at <http://www.data.eaufrance.fr/>.

Supplement

695 The supplement related to this article is available in the attached file (pdf).

Author contribution

700 CG, RL, PR, PC designed the study. CG performed calibration and evaluation of the model, ran the simulations, and wrote the initial manuscript. RL updated the model code of ORCHILEAK to improve representation of soil hydrology and DOC cycling. HZ implemented the representation of manure impacts on soil DOC dynamics into the model code. All co-authors contributed to interpretation of model results and improvement of the manuscript.

705 Competing interests

The authors declare that they have no conflict of interest.
