### Abstract

15 Atmospheric rivers (AR) are important drivers of heavy precipitation events in western and central Europe and often associated with intense floods. So far, the ARs response to climate change in Europe has been investigated by global climate models within the CMIP5 framework. However, their spatial resolution between 1 and 3° is too coarse for an adequate assessment of local to regional precipitation patterns. Using a regional climate model with 0.22° resolution we downscale an ensemble of 24 global climate simulations following the greenhouse gas scenarios RCP2.6, RCP4.5,  
20 RCP8.5.

The performance of the model was tested against ERA-I reanalysis data. The downscaled simulation notably better represents small-scale spatial characteristics which is most obvious over the terrain of the Iberian Peninsula where the AR induced precipitation pattern clearly reflect east-west striking  
25 topographical elements resulting in zonal bands of high and low AR impact. Over central Europe the model simulates a less far propagation of ARs toward eastern Europe compared to ERA-I but a higher share of AR forced heavy precipitation events especially Norway where 60% of annual precipitation maxima are related to ARs.

30 We find ARs more frequent and more intense in a future warmer climate especially in the higher emission scenarios whereas the changes are mostly mitigated under the assumption of RCP2.6. They also propagate further inland to eastern Europe in a warmer climate. In the high emission scenario RCP8.5 AR induced precipitation rates increase between 20 and 40% in western central Europe while mean precipitation rates increase by maximal 12%. Over the Iberian Peninsula AR induced  
35 precipitation rates slightly decrease around -6% but mean rates decrease around -15%. The result of these changes is an overall increased contribution of ARs to heavy precipitation with greatest impact over Iberia(15-30%).

40 Over Norway average AR precipitation rates decline between -5 to -30 %. These reductions most likely the originate from regional dynamical changes. In fact, over Norway we find ARs originating from >60 °N are reduced by up to 20% while those originating south of 45° N are increased. Also, no clear climate change signal is seen for AR related heavy precipitation and annual maximum precipitation over Norway where the uncertainty of the ensemble is quite large.

## 1 Introduction

45 Atmospheric rivers (ARs) are long and narrow corridors that transport large amounts of moisture from  
tropical and subtropical origin poleward (e.g. Zhu et al., 1998; Gimeno et al., 2014; Gimeno et al.,  
2016; Shields et al., 2019). Associated with intense precipitation they can be a strong contributor to  
the local groundwater inventory in regions prone to droughts and thus play an important role for the  
local water management (Lavers and Villarini, 2015; Gimeno et al., 2016), for example in dry areas of  
50 the Middle East or North Africa (Massoud et al., 2020). On the other hand AR induced heavy  
precipitation can likewise cause tremendous economical damage due to flooding (e.g. Gimeno et al.,  
2016; Payne et al., 2020).

Due to their intense moisture load they play an important role for the global water cycle. It has been  
55 estimated that ARs are responsible for >90% of the meridional moisture transport through the mid-  
latitudes (e.g. Gimeno et al., 2016, Gimeno et al., 2018). ARs are associated with extraordinary  
strong low level winds often positioned at the head of a cold front of extra-tropical storm systems (e.g.  
Dacre et al., 2015; Gimeno et al., 2016). Accordingly, they are modulated by large scale weather  
regimes as demonstrated by Pasquier et al. (2019). In the North Atlantic sector the moisture source  
60 for ARs originates mainly from the subtropical Atlantic (Ramos et al., 2016). ARs can occur during the  
whole year but due to their strong linkage to extra-tropical storm systems they are more frequent  
during the cold season in the Northern Hemisphere (Lavers and Villarini 2013; Ramos et al., 2015).

In the North Atlantic and North Pacific Sectors of the World Ocean ARs have been identified as a big  
65 risk for heavy precipitation and flooding along the western coasts of California and Europe (e.g. Ralph  
et al., 2006; Neiman et al., 2011; Ralph and Dettinger, 2012; Lavers et al., 2011, Lavers et al., 2012;  
Lavers and Villarini, 2013; Ramos et al. 2015; Gao et al., 2016, Nayak et al., 2016; Nayak et al.,  
2017). In Europe flooding causes large amounts of economic damages which is expected to increase  
under climate warming (Ashley et al., 2005; Sayers et al., 2015; Alfieri et al., 2016). Therefore, it is  
70 essential to investigate mechanisms that rise the risk for floods (e.g. Kouski 2014; Alfieri et al., 2018).  
For Europe a significant role of ARs in heavy precipitation events and flooding has been  
demonstrated by previous studies. Lavers and Villarini (2013) analyzed atmospheric reanalysis data  
sets and found up to 8 out of the 10 annual maximum precipitation events to be related to ARs during  
the period 1979-2011. Besides their potential to force flooding ARs can contribute significant amounts  
75 of precipitation to the annual total precipitation especially in semi-arid regions and thus can be an  
important source to the local water inventory in regions often threatened by droughts (e.g. Laver and  
Villarini, 2015; Ramos et al., 2016; Gimeno et al., 2016). In Europe most damages associated with  
ARs are located along the western continental margins in particular over the Iberian Peninsula, the  
United Kingdom (UK) and Scandinavia (Laver et al. 2013, Ramos et al., 2015; Whan et al., 2020).  
80 However they also can penetrate far inland and produce heavy rainfall events as far east as in  
Germany and Poland (Lavers and Villarini, 2013).

Because of the larger water holding capacity of a warmer atmosphere it has been suggested that  
climate warming will increase the risk for intense flooding (e.g. Held and Soden ,2006). Lavers et al.  
85 (2015) demonstrated that the intensification of the global water cycle due to climate warming  
strengthens the mean atmospheric water transports over the North Atlantic by 30 – 40%. So far,  
assessments of AR related flood risk in a future warmer climate are primarily based on climate  
projections from global climate models (e.g. Lavers et al., 2013; Lavers et al., 2015; Warner et al.,  
2015, Ramos et al., 2016; Gao et al., 2016; Espinoza et al., 2018; Whan et al., 2020). Lavers et al.  
90 (2013) showed an intensification of AR in terms of frequency and intensity in future climate based on  
the analysis of five CMIP5 global models. Ramos et al. (2016) found a doubling of AR frequency  
together with an increase of moisture load in the RCP4.5 and RCP8.5 scenarios in six CMIP5 models  
at the end of the 21<sup>st</sup> century compared to the historical period. Gao et al. (2016) analyzed an

95 ensemble of 24 CMIP5 global models and found a pronounced increase in the contribution of AR  
related precipitation to the total annual precipitation in a future warmer climate following the RCP8.5  
scenario. Whan et al. (2020) recently used the high resolution version of the CMIP5 EC-Earth model  
to study the climate change impact on AR induced precipitation over Norway. They indicated that up  
to 80% of the winter maximum precipitation is associated with ARs. They also found the magnitude of  
extreme precipitation events to be mainly controlled by AR intensity.

100

#### Purpose of this study

105 The majority of global models currently employed in the CMIP5 and CMIP6 framework employed  
provide a resolution typically ranging from 1.4° to 3° allowing a robust analysis of the large scale  
impact on continental scale precipitation. However, they do not fully resolve small scale  
characteristics which is necessary to assess the local impact on AR related precipitation patterns.  
Here, we investigate how far downscaled high resolution regional projections can improve the  
representation of ARs on the regional scale and thus add value to global assessments.  
For Europe such regional assessments are still lacking. Here we analyze for the first time a regional  
110 climate ensemble for Europe based on a horizontal resolution of 0.22°. We use this ensemble to  
analyze future changes in AR frequency and AR induced heavy precipitation pattern over Europe and  
their implication for the local water budget. We likewise aim to assess climate induced changes in the  
regional pathways of ARs on their journey across Europe. Finally, we assess uncertainties with  
respect to 3 different climate scenarios (RCP2.6, RCP4.5, RCP8.5) and 9 different global climate  
115 models from the CMIP5 suite.

The paper is outlined as followed: Section 2 briefly describes the regional climate model RCA-NEMO  
as well the AR detection procedure. Section 3 provides a validation RCA historical ensemble with  
respect to ARs for the present-day period and investigates the added value of high resolution. Section  
120 4 analyzes future changes in AR frequencies and the impact on precipitation under different climate  
scenarios. Section 5 discusses uncertainties with respect to the choice of the driving global model.  
Main conclusions are summarized in section 6.

## **2. Methods**

### **125 2.1. The regional climate model RCA-NEMO**

The regional climate model (Wang et al., 2015; Gröger et al., 2015; Dieterich et al., 2019) consists of  
the Rossby Center regional atmosphere model RCA (Samuelsson et al., 2011; Kupiainen et al., 2014)  
version 4 coupled to the Ocean General Circulation model NEMO (Table 1, Nucleus for European  
130 Modelling the Ocean NEMO, Madec, 2012). RCA is a hydrostatic atmosphere model which is set up  
for this study according to the Euro-Cordex domain (Fig. 1). The horizontal resolution is 0.22 degrees  
on a rotated grid yielding grid cell sizes between 550 – 600 km<sup>2</sup> (Table 1) and the vertical  
discretization is given by 40 hybrid levels. At the lateral boundaries the model is driven by data from  
either reanalysis data sets or global climate model output. The forcing data are prescribed at 6-hourly  
135 time intervals. The land surface boundary is prescribed by ECOCLIMAP (Champeaux et al., 2005) and  
used to calculate the land - air mass and energy fluxes. Different to the majority of the EURO-Cordex  
high resolution ensembles (Jacob et al., 2014), RCA is interactively coupled to the 3D ocean model  
NEMO. The coupling area comprises the North Sea and the Baltic Sea. Over this region sea ice  
temperature, sea ice fraction, sea ice albedo, and water temperature is explicitly modeled by NEMO  
140 and communicated at 3-h time steps to RCA. Air – sea mass and energy fluxes are then calculated in  
the atmosphere model and used to drive NEMO which is set up in a resolution of 2 nautical miles  
(~3.7 km) and 56 vertical varying z\* layers. The coupling is managed by the OASIS coupler (Valcke et

145 al., 2003). Outside the coupled domain, i.e. the Mediterranean and the North Atlantic, RCA is driven by reanalyses data in the hindcast case or by global climate model output. Sea ice fields are explicitly modeled by the Louvain-la-Neuve sea ice model LIM3 (Vancoppenolle et al., 2008).

Model system	Atmosphere component	Ocean component	Domain size Atmosphere	Domain size ocean model	Grid resolution atmosphere	Vertical levels
RCA-NEMO	RCA	NEMO3.3.1	Euro-Cordex	North Sea, Baltic Sea	550-600 km <sup>2</sup>	40
ERA-I	IFS (Cy31r2)	Prescribed SSTs	global	global	6400 km <sup>2</sup>	60

Table 1: Climate model configuration employed in this study. Also shown is the analyzed data set from the ERA-I reanalysis

150 RCA-NEMO has been intensively validated and comprehensively described in detail (e.g. Wang et al., 2015; Gröger et al., 2015; Dieterich et al., 2019; Gröger et al., 2019; Gröger et al., 2021a). It has been employed in large ensembles to study the present climate and to simulate the mean response to global climate change by downscaling global climate scenarios in a huge ensemble (Dieterich et al., 2019; Gröger et al., 2019; Gröger et al., 2021a). Gröger et al. (2021a) showed that the RCA-NEMO coupled ensemble is well within the range of the high resolution Euro-Cordex ensemble (Jacob et al., 2014). However, significant differences arise over interactively coupled areas over sea (Gröger et al., 2021a; Gröger et al., 2021b). This applies to both climatic mean changes, as well as climatic extremes (e.g. dry periods cold spells, heat waves etc).

Figure 1: Model domain showing the topography of the RCA-NEMO climate model. Bathymetry information indicates the domain of the interactively coupled ocean model NEMO.

## 2.2 The high resolution ensemble

160 The above described model was used to downscale a suite of global model climate scenarios taken from the Coupled Model Intercomparison Project phase 5 (CMIP5, Taylor et al., 2012). Table 2 lists the individual realizations and primarily distinguishes the applied scenarios (first row) and individual model configurations (first column). In addition to the used global climate models we also analyze a hindcast simulation forced by ERA-I reanalysis data to validate the model for the present day climate  
165 (1979-2009) of the ensemble is provided by RCA which comprises 34 runs including one ERA-I

hindcast run.

Reg.Mod – Glob. model	historical	RCP2.6	RCP4.5	RCP8.5
RCA – MPI-ESM-LR	x	x	x	x
RCA – EC-EARTH	x	x	x	x
RCA – HadGEM2-ES	x	x	x	x
RCA – IPSL-CM5A-MR	x		x	x
RCA – GFDL-ESM2M	x	x	x	x
RCA – CanESM2	x		x	x
RCA – CNRM-CM5	x		x	x
RCA – NorESM1-M	x	x	x	x
RCA – MIROC5	x	x	x	x
RCA – ERAI	x			

Table 2: List of 34 coupled regional simulations grouped by greenhouse gas scenarios and downscaled global models.

170

The chosen climate scenarios follow the protocol of Representative Concentration Pathways (RCP) used in CMIP5 and comprise three different greenhouse gas assumptions. One low emission scenario assumes vigorous mitigation actions (RCP2.6 van Vuuren et al. 2007, 2011) and was developed in regard to limit the global mean temperature to 2 °C warming since the pre-industrial period. It

175

assumes negative emission during the last decade of the 21<sup>st</sup> century. RCP4.5 is a moderate scenario where emissions peak at the mid-century (2040) and are kept constant after ~2080 at a value about half of the value at the end of the historical period (Clarke et al. 2007; Thomson et al. 2011). Finally, a totally unmitigated scenario RCP8.5 (Riahi et al. 2007; Riahi et al., 2011) assumes rising emissions up to the end of the century. The three scenarios impose a maximal radiative forcing of 2.6, 4.5, and

180

8.5 W/m<sup>2</sup> compared to pre-industrial conditions.

### 2.3 Detection of atmospheric rivers

185

The detection procedure of ARs is briefly described below and was performed for 30 year periods at the end of the 20<sup>th</sup> century (1970-1999) and at the end of the 21<sup>st</sup> century (2070-2099) i.e. for each of the RCP2.6, RCP4.5, and RCP8.5 individually. Only the RCA-ERA1 hindcast run was done for 1979 to 2009.

190

Atmospheric river detection can be basically done using their specific characteristics, namely the extraordinary moisture transport and their elongated shape (width and length scales). A number of studies addressed methods to detect ARs in model simulations and gridded reanalysis data (Lavers et al., 2011; Lavers et al., 2012; Nayak et al., 2014; Nayak and Villarini, 2016; Gao et al., 2015; O'Brian et al., 2020). An overview can be found in Guan and Waliser (2015). We here employ the detection algorithm developed by Laver et al. (2012) and Lavers and Villarini (2013) which has been

195

successfully applied both for hindcast simulations and climate studies (Lavers and Villarini, 2012; Lavers et al., 2013). First, the vertically Integrated atmospheric water Vapor Transport (hereafter IVT) is calculated at every model output time step. The vertical integration is done over the models pressure levels from 1000 to 300 hPa that were converted from the models hybrid levels:

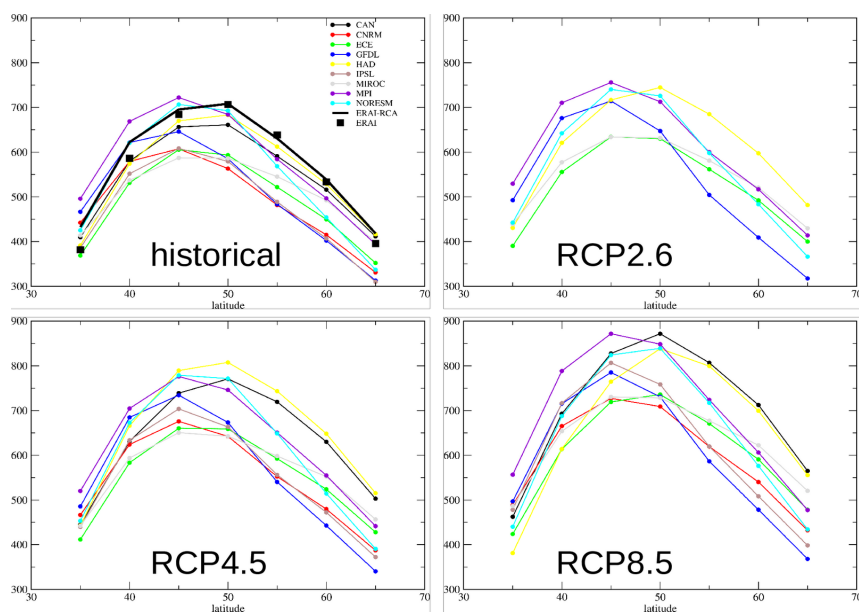

$$200 \quad IVT = \sqrt{\left(\frac{1}{g} \int_{1000}^{300} qu dp\right)^2 + \left(\frac{1}{g} \int_{1000}^{300} qv dp\right)^2}$$

where  $g$  is gravitational acceleration,  $q$  is specific humidity kg/kg,  $u$  and  $v$  the horizontal wind components and  $dp$  the pressure level difference of adjacent pressure levels. In the two hydrostatic models' hybrid level space, the IVT is balanced by precipitation minus evaporation.

205

Then the 85<sup>th</sup> percentile IVT is calculated based on IVTs at 12:00 UTC time stamps and along 10 °W longitude (Lavers and Villarini 2012; Lavers et al. 2013). Following Lavers et al. (2013) this procedure is done for meridional bins of 5° between 35-70°N. The resulting 85th percentile values served then as threshold for the detection of ARs (Fig. 2). After this pre-processing all 6-hour IVT fields are analyzed along 10 °W and the 5 ° latitudinal bins at every single output time step. If the max IVT within an individual bin exceeded the threshold for that bin (Fig. 2) a westward and eastward search was done starting from 10°W to 30°W and 25 °E. All grid cells where the threshold was exceeded were retained (Lavers and Villarini, 2013).

210

215

Figure 2: IVT thresholds [ $\text{kg m}^{-1} \text{s}^{-1}$ ] for the ensembles' historical period (1970-1999, upper left) and RCP climate scenarios (2070-2099) at 10°W used by the algorithm to track ARs..

220

Next, the resulting fields are further evaluated for spatial and temporal criteria (Lavers and Villarini, 2013). Hence the axis of a potential AR was determined as maximum along each longitude IVT of the structure. Only those fields were retained with an axis longer than 1500 km and then classified as AR. Furthermore, an AR has to be persistent over a period of at least 18 hours. Figure 3 shows a prominent example for an AR detected in the ERA-I reanalysis (left) and the ERA-I hindcast simulation (right) that demonstrably caused intense rain over Europe (Lavers and Villarini, 2013). The

225

Figure 3: Atmospheric river associated with storm Lothar detected in the ERA-I reanalysis (left) and the ERA-I hindcast simulation (right), 25 December, 1999; 0:00:00 UTC. IVT values below the threshold are masked out.

### 3. ARs in the historical climate

#### 3.1 General statistics

230 Table 3 summarizes the frequency of atmospheric rivers (expressed as total ARs detected in a 30-year period and along 10°W) for each run of the ensemble as well as from the ERAI reanalysis data set and the hindcast run. The number of detected ARs in the RCA-ERAI hindcast (322) is nearly identical with that analyzed from the ERAI reanalysis (321) itself which was used to drive the model. This indicates that the number of ARs in RCA is primarily controlled by the lateral boundary  
235 conditions. This is not surprising since ARs develop in open ocean regions far outside the model domain and so the potential for alterations by the regional model is quite low. According to this, the number of detectable ARs in the individual RCA historical climate simulations (Table 3) will likewise reflect the ARs generated from the driving global climate model. Consequently, the RCA historical climate ensemble exhibits a fairly large spread during the historical period ranging from 262 (RCA-  
240 MIROC) to 421 (RCA-NORESM). The difference between the ensemble mean of RCA historical simulations (RCA-MEAN=359) and the RCA-ERAI hindcast run (n=322) is quite low compared to the standard deviation over the RCA historical ensemble (58).

245

	HISTorical/ Hindcast	RCP26	RCP45	RCP85
RCA-ERA1	322			
ERA1 reanalysis	321			
<b>RCA-NEMO climate ensemble</b>				
RCA-MEAN	359	390.0 (+8.6)	425.7 (+18.56)	445.6 (+24.1)
RCA-STD	58	67.4 (+16.46)	71.50 (+23.57)	90.3 (+56.0)
RCA-MPI	304	311 (+2.3)	350 (+15.1)	392 (+29.0)
RCA-HAD	397	422 (+11.3)	484 (+21.9)	565 (+42.3)
RCA-ECE	393	396 (+0.76)	412 (+4.8)	468 (+19.1)
RCA-GFDL	351	367(+4.6)	388 (+10.5)	456 (+29.9)
RCA-IPSL	409		498 (+21.8)	523 (+27.9)
RCA-CAN	367		445.8 (+21.3)	447 (+21.8)
RCA-CNRM	285		317 (+11.2)	362 (+27.0)
RCA-MIROC	262	264(+0.76)	302 (+15.3)	276 (+5.3)
RCA-NORESM	421	417(-0.91)	457 (+8.6)	521 (+23.8)

Table 3: Frequency expressed as number ARs detected in a 30 year period of different climate scenarios. The historical period is for all runs 1970-1999. Only for the ERA1 runs it is 1979-2009. Numbers given in parenthesis denote relative change [%] in the future period compared to the historical period.

Figure 4a compares the moisture transport by ARs over land which indicates the potential to force local heavy precipitation events. We note that the RCA-ERA1 run has a lower moisture content over land compared to ERA1 (~5%, Figure 4a). This is in line with the models cold bias in air temperature (Gröger et al., 2021a) which favors lower moisture contents. The probability distribution of diagnosed AR durations (Figure 4b) indicates no systematic differences between the ERA-I reanalysis, the hindcast run or the mean historical climate simulations. For all model realizations about half of the detected AR last for less than one day (Fig. 4). Noteworthy is the lower moisture content of nearly the entire RCA historical ensemble compared to the RCA-ERA1 hindcast simulation. Overall, this points to a systematic negative bias in moisture contents over land in the RCA model.

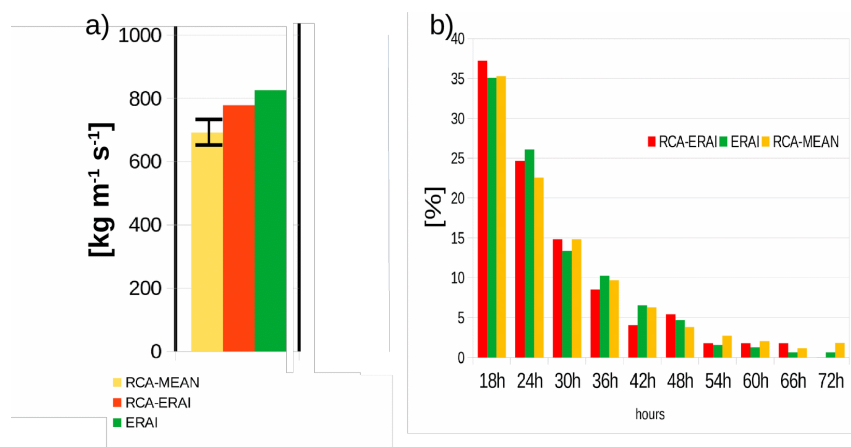

Figure 4: a) Average moisture transport over land by ARs for each model realization depicted from the climatological historical period (RCA-MEAN) as well as for the hindcast simulation (RCA-ERA1) and the reanalysis data set (ERA1). For RCA-MEAN the range of two standard deviations from individual realizations is given. b) Histogram of average durations of detected ARs.

### 3.2 Impact on precipitation

260 In a first step we estimate the likelihood for a certain region to be affected by an AR. As a simple  
 index, we count the total number of days during which a land cell was covered by an AR (AR days,  
 Figure 5a). As expected, ARs are most present over the UK and the coastal regions of western  
 Europe. Further inland the AR imprint declines as ARs lose moisture due to rainfall and thus do not  
 265 further meet the IVT threshold (Fig. 2). Strong moisture loss is also indicated along the Norwegian  
 coast where the landfall of ARs cause strong rain events due to uplift.

Next we quantitatively evaluate the imprint of ARs on extreme precipitation by calculating the portion  
 of yearly maximum of daily precipitation that is caused by ARs. The result is shown in Fig. 5b which  
 shows the percentage of yearly maximum daily precipitation rates forced by ARs. ARs explain up to  
 270 ~60% of the yearly maxima precipitation rates over southwestern Norway. A strong imprint is likewise  
 seen over western UK and along the European coasts.

275

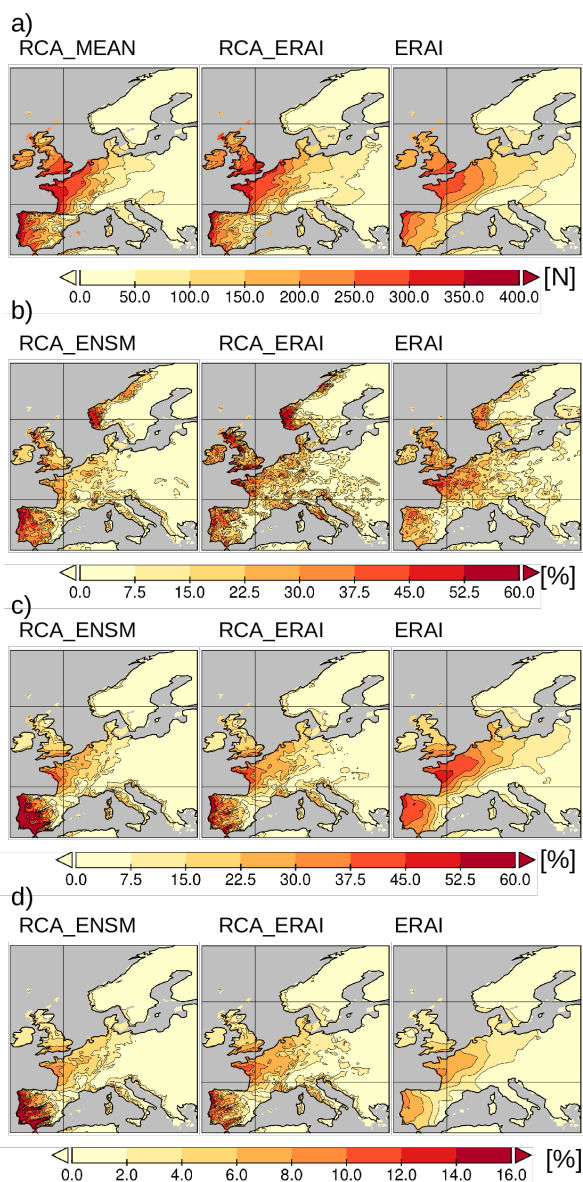

Figure 5: a) AR frequency expressed as total number of days grid cell was covered by an AR during the historical period. b) Percentage of annual maximum precipitation related to ARs. c) contribution of AR forced precipitation to the >95th percentile precipitation. d) same as c) but for the total precipitation

Besides their potential to force yearly precipitation maxima ARs strongly affect the fraction of heavy precipitation events. Here we investigate the AR contribution of precipitation to the total annual precipitation (Figure 5d) and to the fraction of heavy precipitation (Figure 5c). The spatial pattern

280 mainly resembles the pattern seen in the AR days (Figure 5a) but further reflects the mean climatic  
conditions in Europe. In humid regions of central and western Europe, AR related rain contributes  
up to 40% (Bretagne) to the >95th percentile precipitation. These are also the regions which are  
frequently affected by ARs (Fig. 5a). In semi-arid regions like the Iberian Peninsula the contribution  
increases to almost 60% which compares well with results from gridded reanalysis data sets  
(Lavers and Villarini, 2015). A considerable contribution is likewise seen along the western coast of  
285 Italy. Here AR contribution is up to 30 % (Fig. 5d) although ARs do not notably cause annual  
maximum precipitation rates (Fig. 5b). In the topographically elevated regions of Norway and over  
the Alps, i.e. regions supporting often strong convective rain events, the influence of ARs is also  
less pronounced. As expected in more humid regions of eastern Europe and Scandinavia ARs  
contribute only minor amounts to the annual total. A similar pattern is shown for the contribution to  
290 the total annual precipitation (Figure 5d). Maxima contributions are seen over western France and  
the western Iberian Peninsula where ARs contribute up to 10% to the total precipitation.

### 3.2.2 Comparison of the RCA ensemble mean with the ERAI hindcast and ERAI reanalysis

295 In the historical simulations, i.e. when the model is forced by climate output the regional coupled  
models develop their own weather regimes which can not be expected to be in phase with  
recorded weather data. Therefore, individual AR incidences can be analyzed only statistically  
which is done in terms of calculated indices during the climatological historical period (Fig. 5).  
We now compare the results of the RCA historical ensemble mean (Figure 5, left column) with the  
300 RCA-ERAI hindcast (Figure 5, middle column) and the ERAI reanalysis data (Figure 5, right column)  
in which internal natural variability can be expected to reflect the observed weather. Figure 5  
demonstrates that for most of the above described indices the RCA historical ensemble mean  
represents reasonably well the spatial pattern found in the RCA-ERAI simulation. The spatial  
correlation coefficients between RCA-ERAI and RCA-ENSM are respectively calculated as 0.98  
305 for AR the frequency (Fig. 5a), 0.82 for the percentage of yearly maximum precipitation (Fig. 5b),  
and respectively 0.92 for contribution to total annual and heavy rain precipitation amount (Fig.  
5c,d).

310 Besides the spatial pattern seen in the AR indices, the detected ARs also undergo a strong  
seasonal cycle. Figure 6 shows that ARs are most abundant during fall and early winter. A  
pronounced difference is, however, seen in August where the relative share is about twice as much  
in the RCA historical ensemble compared to the ERAI hindcast which implies that the AR season  
starts a bit too early in the RCA ensemble. However, all in all we find that spatial patterns and the  
seasonal cycle of ARs is well preserved in the models climate mode compared to the ERAI data  
315 set and the ERAI hindcast.

Figure 6: Seasonal cycle of detected ARs expressed as percentage share of total number of detected AR. The reference period for the RCA historical ensemble (blue) is 1970-1999 and for the ERA1 hindcast (orange) and ERA1 (yellow) reanalysis it is 1979-2009.

320

### 3.2.3 Effect of regionalization

The above described spatial characteristics is also well reflected in the ERA1 reanalysis data (Fig. 5, left column). However, the lower spatial resolution of this data set (approx. factor of 10, Table 1) destroys much of spatial variation which demonstrates the effect of the downscaling by RCA. This is more visible in the precipitation related indices (Fig. 5b-d) than in the AR frequencies (Fig. 5a). This is expected as precipitation patterns are modulated by stochastic processes and further modulated by topography while the integrated atmospheric moisture transports (used to detect and track ARs) are less affected by small scale patterns.

330

The added value of regionalization is demonstrated by the comparison between the high resolution RCA-ERA1 run with a resolution of 0.22° and the corresponding ERA1- data set with a resolution of 0.75°. First, the downscaled RCA-ERA1 run shows notably higher AR frequencies and larger contribution to the total precipitation (and >95<sup>th</sup> percentile precipitation) along the coasts compared to the original ERA1 data set (Fig. 5a,c,d). In turn, AR frequencies in the distal parts of eastern Europe are higher in the reanalysis data than in the ERA1 hindcast run. This implies ARs tend to penetrate less far inland after landfalling in the downscaled run. Apart from this, the downscaling effect is most pronounced in regions with elevated topography as well as in semi arid climate zones of southern Europe. Over Iberia the RCA-ERA1 run clearly resolves the distinct effect of the west – east striking topographic features seen in the contributions to the precipitation budgets. They occur as small WSW-ENE striking bands of alternating high and lower AR precipitation following the topographic elements build up by the Sistema Central Plateau, the Sierra Morena mountains, and the Penibaetic orogenic system (Fig. 5c,d). Furthermore, the local maxima of AR contributions seen along Italy are by far less pronounced in the coarser ERA1 reanalysis (Fig. 5c,d). Apart from this, we also find a notably lower amount of annual precipitation maxima related to ARs

345

(Fig. 5b). Over Norway the difference can be as large as 15 %. Here, the lower resolution likely smooths heavy precipitation events.

Another slight but noteworthy RCA-ERA-ERA vs ERA-ERA difference is seen in the seasonal distribution of ARs. In the RCA-ERA-ERA hindcast the fall maximum is already registered in September while in ERA-ERA it is recorded for October. The most likely explanation for this is a temperature bias introduced by RCA. Gröger et al., (2021a) showed that RCA has a negative temperature bias against the observational E-OBS data set. This means that air masses enter the lateral model boundary with a thermodynamically too high moisture load. The adaptation, i.e. the loss of moisture when the air masses are confronted with the mean thermodynamics state of the inner RCA-domain, probably takes longer for fast moving air masses like within ARs. This would favor the detection of too many ARs.

Finally, we note that the global CMIP5 models used to drive RCA have an even lower resolution ranging between 1.4° (CNRM) and 3° (CAN) which is notably lower than the ERA-ERA reanalysis data set. This implies that the added value of regionalization in the future scenarios can be expected of even greater importance.

## 4. Future climate change impact on ARs

### 4.1 General response of AR frequency and intensity

Figure 7 summarizes the relative change in average moisture transport by ARs according to the different greenhouse gas scenarios and for each of the downscaled global models. Consistently, ARs become more intense i.e. they have a higher moisture load in a warmer climate. The intensity at the end of the century increases on average by 9% (RCP2.6), 13% (RCP4.5), and 24% (RCP8.5) which is more or less in line with the corresponding increases of IVT thresholds (Fig. 2).

Besides intensity, also the frequencies of detected ARs increases (RCP2.6=8.6%; RCP4.5=18.6%, RCP8.5=24.1%, Table 3) which are roughly proportional to the increase in intensity. However, not only the frequency of ARs increases but also the spread of the individual realizations at the end of the century. The relative change in ensemble spread (Table 3, 2nd row) increases even more than the ensemble average (RCP2.6=16.5%, RCP4.5=23.6%, RCP8.5=56.0%). This highlights the large uncertainty with respect to the chosen global model used for downscaling. Some advanced approaches for weighted model averaging were developed to reduce this type of uncertainties and have been tested for the case of AR over the US (Massoud et al., 2019; Massoud et al., 2020, Wootten et al., 2020).

Figure 7: Relative change in moisture transport within ARs at the end of the century (2070-2099) compared to the historical period (1970-1999).

#### 4.2 Spatial changes

Next we analyze spatial pattern changes in future AR imprint. First, AR frequencies are addressed. Figure 8a demonstrates an overall increase in the frequency of AR days which is strongest over in the southwestern sector of the Atlantic (Biscay) and adjacent land areas with maximum response over western France and the southern UK. This pattern is more or less consistent across the RCP scenarios but differs in strengths ranging from ~+20% to more than 200% (Fig. 8a)

We now investigate how the increased AR frequencies influence precipitation patterns. In a first step the impact on the AR forced yearly maximum precipitation is addressed (Fig. 8b). The most robust change is the strong increase over the western central part of Europe which extends from western France along the coast of Belgium, the Netherlands northern Germany and Denmark up to the southern coast of Norway. Further spots of stronger AR impact are also visible along the northwestern tip of the Iberian Peninsula and the southern part of the UK. This general response is by far strongest in the unmitigated RCP8.5 scenario. In the moderate scenario RCP4.5 the changes are less pronounced in eastern central Europe (Germany, Denmark). In the mitigation scenario RCP2.6 notable robust changes are restricted to a small area in NW France (Bretagne, Normandy). Over southern Scandinavia where the highest values are found during the historical period (see Fig. 5b) no robust changes are detected.

Next we address the number of AR forced heavy precipitation events. Figure 8c shows the number of events nearly everywhere increases. The strongest response is seen over southern Scandinavia where the relative increases exceed 300%. Over the western European continent and the UK the average increases are in the range between 75-150% pointing to a roughly doubling risk for flooding. Apart from this very strong increases (>300%) are noticed over eastern Europe (Figure 8c). Although in this region absolute AR occurrences are rather low, the strong relative increases indicate a further eastward propagation of AR under the warmer future climate compare to present day.

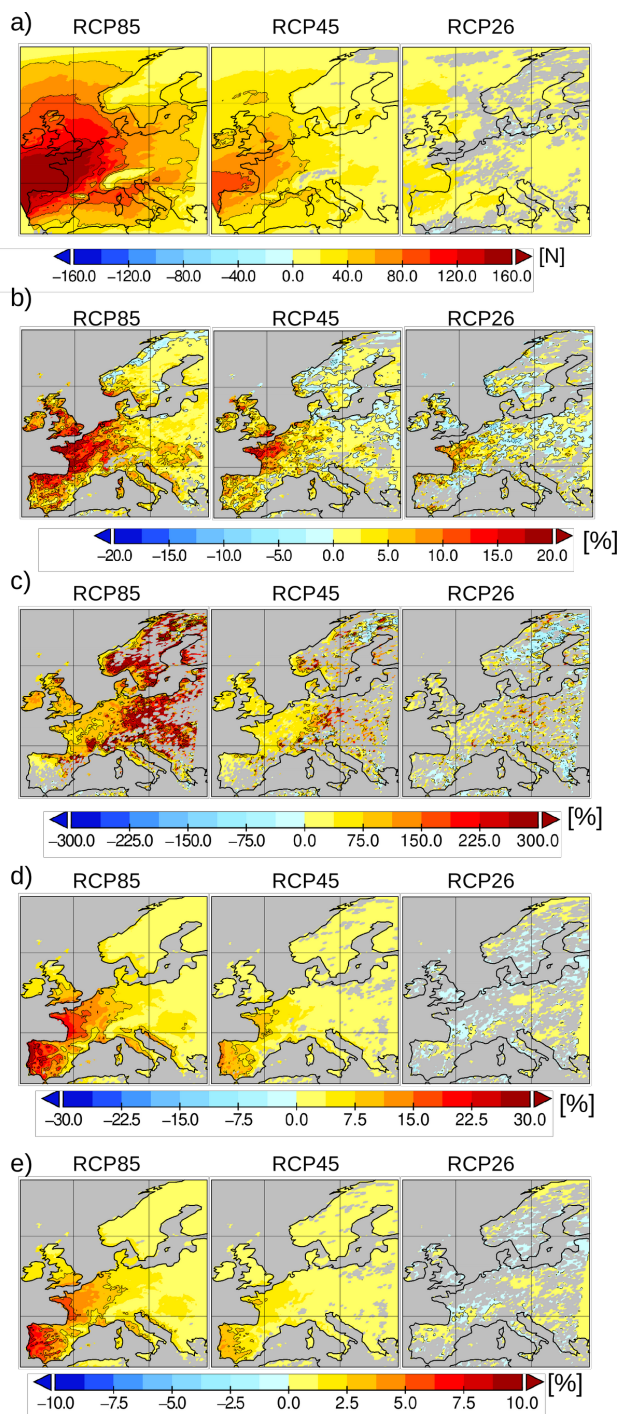

Figure 8: Difference between 2070-2099 minus 1970-1999 climatological indices for the RCA ensemble. a) AR days frequency b) AR forced yearly maximum precipitation rates. c) Number of AR forced rain events within > 95th percentile fraction d) Change in the contribution of AR forced precipitation to the heavy rain fraction (total >95th percentile precipitation). e) same as d) but for the contribution to the annual total precipitation. Note all non-robust changes (at least 66% of downscaled runs agree on the sign of change) have been masked out. For b) – e) only changes over land are shown.

410

The higher AR frequencies and moisture loads have also consequences for the local precipitation budget. Figures 8 displays the changes in the contribution of ARs to the heavy precipitation fraction (Fig. 8d) and the total annual precipitation (Fig. 8e). Most pronounced changes are seen in regions where already under historical climate condition large contributions are seen (Fig. 5c,d). Strongest increases are primarily seen over Iberia with changes up to +30% to the heavy rain precipitation and up to 20% along the French coast (Bay of Biscay) compared to the historical period.

415

At least for the moderate and high greenhouse gas scenarios RCP4.5 and RCP8.5 the contribution-anomalies are robustly positive (Fig. 8d,e). The positive anomalies imply that in these regions the AR induced precipitation rates increase stronger than mean precipitation rates.

420

The different response of mean precipitation and AR induced precipitation to climate change is depicted in Figure 9. The climatological mean change (Figure 9a) shows the typical change in precipitation over Europe pointing to dryer conditions over southern Europe and wetter conditions over northern Europe (e.g. Jacobs et al., 2014; Kjellström et al., 2018; Teichmann et al., 2018; Gröger et al., 2020a; Christensen et al., 2021). Hence, mean precipitation rates increase only slightly by up to maximal 12 % over central Europe or even decrease over southern Europe. By contrast, AR induced precipitation increases between ~25 – 40% over central Europe (Fig. 9b). In fact AR induced precipitation ranges are in most regions equally high as mean winter precipitation changes (not shown), i.e. the season where mean changes are highest. Also decreasing AR precipitation is found in southern Europe but the reductions are less strong compared to mean rates. The only exception is Norway where in fact AR induced precipitation decreases while mean rates increase. This likewise explains the low response of annual maximum changes (Fig. 8b).

430

435

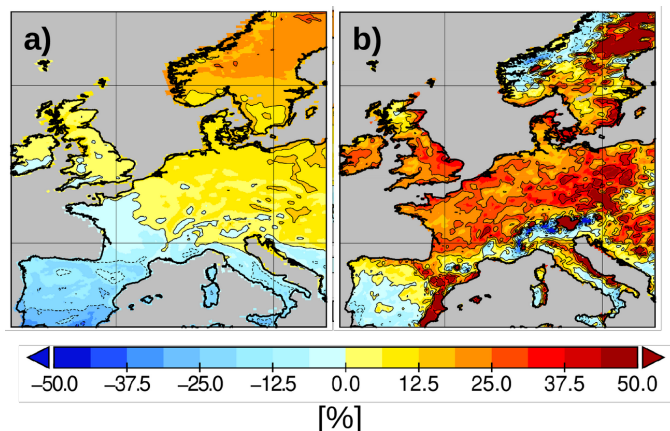

Figure 9: a) Relative change in mean precipitation rates for RCP85. b) Relative change in AR induced precipitation rates.

### 4.3 Influence of potential dynamical changes

440 In the mid to high latitudes it has been found, that climate changes in mean and extreme precipitation  
takes place at similar magnitudes and mainly reflect thermodynamical processes (i.e. increasing water  
carrying capacity with warming air, e.g. Emori and Brown, 2005). Exceptions from this occur only  
when large scale circulation changes with further impact on moisture transport are involved (Emori  
and Brown, 2005). Based on global CMIP5 models Gao et al. (2016) suggest that thermodynamics is  
445 also the main driver AR related precipitation changes but may be modulated by dynamical circulation  
changes due to changes in the Jet position.

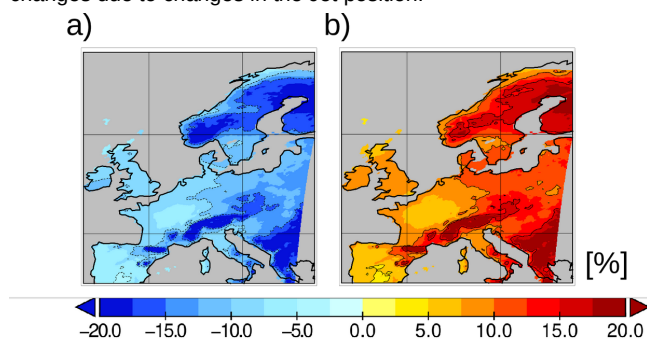

Figure 10: Analysis of AR origin in the RCA ensemble. a) Relative contribution of regional AR occurrences originating from the Atlantic north of 60°N. b) same as a but for ARs originating from south of 45°N. Shown is the change for RCP8.5 (2070 - 2099 minus 1970-1999).

In order to investigate potential dynamical changes we now elaborate more about the pathway of ARs on their way from the open ocean to the continent. It is not feasible to analyze the movement of every single AR over time. Instead, we here perform a simple analysis to determine the AR source region for every AR. Hence we check for every AR incident registered on land at which latitude the AR entered the European sector along 10°W meridian. We here consider the latitudinal bins south of 45°N, 45-60°N, and north of 60°N. From this statistic we calculated for every land cell the percentage share of AR incidents for every latitudinal band (so that the sum of all bins at every land point sums up to 100%). The analysis is done for high emission greenhouse gas scenario RCP8.5 compared to the historical period.

Figure 10 shows the change in the relative contribution for the latitudes south of 45°N (Fig. 10a) and north of 60°N (Fig. 10b). Overall, the RCA ensemble clearly shows a relative increase of those ARs originating south of 45°N degree (Fig. 10a). Most prominent increases are seen over the Alpine region and Scandinavia whereas western and central Europe are less affected. Between 45 and 60°N the changes are everywhere below 5% (not shown) indicating a more or less unchanged contribution within this latitudinal band.

By contrast, AR contributions from >60°N are diminished (Fig. 10b). Over Scandinavia ARs from >60°N contribute around 70-90% to the total AR events during the historical period (not shown). This contribution is reduced by ~20% in RCP8.5 (Fig.10b) and thus likely explains the aforementioned

470 decreased AR precipitation rates (Fig. 9b). Hence, for Scandinavia this implies a profound southward  
shift in the origin of ARs that cross Scandinavia. In turn, this shift suggests that the moisture has to be  
transported over a longer distance across the central continent compared to those ARs originating  
from  $>60^{\circ}\text{N}$ .

475 In summary, we can conclude that ARs from the southern Atlantic sectors are more present over most  
land regions in a warmer climate. By contrast, ARs arriving from the northern sectors of the Atlantic  
are relative diminished over land (Fig. 10b).

## 5 Discussion

### 5.1 Uncertainties with respect to the global driving CMIP5 models

480 We now investigate individual ensemble members for a selected set of indices, namely, the changes  
in AR days frequency, the annual maximum precipitation, and the contribution of ARs to the yearly  
total heavy precipitation.

485 Figure 11a depicts the frequency of ARs. All realizations exhibit a highly coherent spatial pattern  
which is similar RCA ensemble mean (Fig. 8a) indicating the latter as a representative indicator for the  
bulk response. The model spread as summarized by the ensemble standard deviation asserts highest  
uncertainties in two latitudinal bands north of  $40^{\circ}\text{N}$  and north of  $55^{\circ}\text{N}$  in the North Atlantic. A  
notably strong increase over the North Atlantic is registered for the RCA realizations for RCA-HAD,  
RCA-IPSL, and RCA-MPI while RCA-MIROC and RCA-ECE show a particularly weak signal. RCA-  
ECE show a distinct separation into a northern and southern core zone of increased AR presence.  
490 Notably, one realization shows wider areas of decreased AR presence in the high latitude Atlantic  
(RCA-MIROC).

495 The response of AR forced annual maximum precipitation events is shown in Figure 11b. No clear  
consistent response is registered over the topographic elevated region of western Norway i.e. the  
region which is most impacted by ARs in the historical climate (Fig. 5b). Some models show distinct  
locations with decreased AR impact over Norway (e.g. RCA-MPI RCA-GFDL, RCA-IPSL) which is  
probably linked to the aforementioned decrease of ARs arising from  $>60^{\circ}\text{N}$ . The most coherent  
change across the realizations is the more or less strong increase over the western France which in  
some realizations extends further to the east. However, also in this region local ensemble variability is  
500 pronounced and in RCA-ECE even a decrease is seen. The pronounced ensemble variability is not  
unexpected because the yearly maxima represent the most heavy precipitation events over a certain  
region.

505 Uncertainties with respect to the contribution to the heavy precipitation budget is highest in the region  
of largest changes (Fig. 11c). High inter-model variance is found for the southern tip of Iberia  
indicated by maximal standard deviations. In this region the contribution can either be reduced as in  
RCA-HAD or increased as high as +50% as in RCA-CNRM. The same change pattern is likewise  
seen in Italy but with a lower magnitude. Higher uncertainties are likewise found for central Europe  
(France, Belgium, Netherlands, Germany). This mainly reflects the different inland penetration of ARs  
510 in the models response to climate change. In case of RCA-MIROC and RCA-ECE this results in only

very low change (<5%) for wide regions of France and Germany. With respect to the UK only one model RCA-HAD shows notable reductions of AR contributions over the UK.

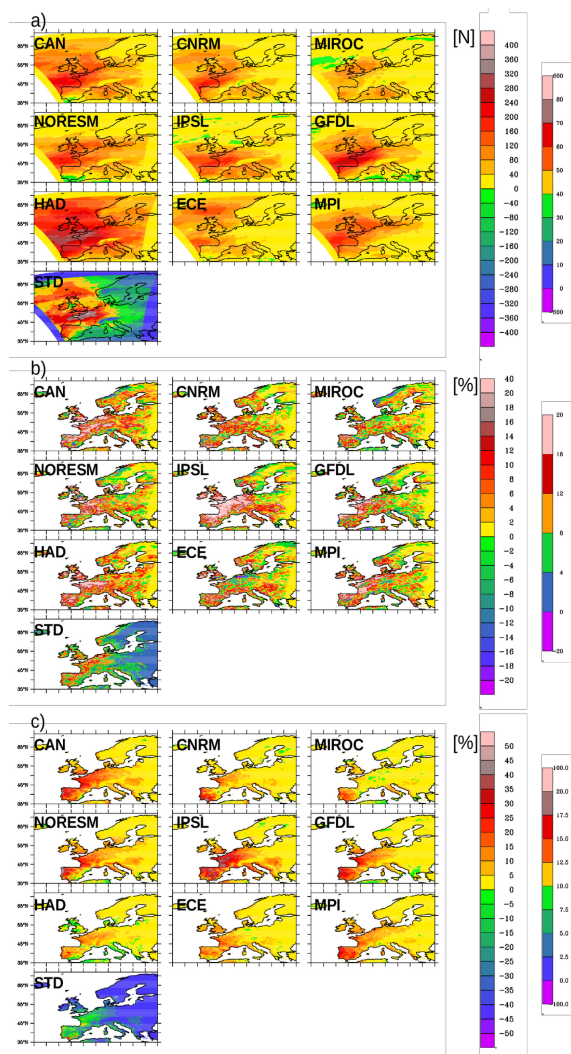

Figure 11: Change in frequency (2070-2099 minus 1970-1999). b) same as a) but for percentage in AR forced yearly maximum precipitation., c) same as a) but for AR contribution to heavy precipitation events (>95th percentile). Note the RCA realization are denoted by their forcing global model simply. STD denotes the inter-model standard deviation. Long bars indicate the color scale of the ensemble member indices. Short bar is for inter-model standard deviation)

515 In summary we can conclude that the ensemble members robustly agree on a stronger future AR  
 impact on heavy precipitation over western central Europe with a hot spot over NW France and further  
 extension eastward depending on the realization.

## 5.2 Differences to global projections

Our results generally agree with results from global CMIP5 models (e.g. Gao et al., Lavers et al., 2016; 2016; Ramos et al., 2016) that ARs become more frequent and intense. With respect to  
520 previous studies we note that the climate change effect on AR frequency strongly depends on the  
chosen reference period. Studies that employ the 85<sup>th</sup> percentile threshold derived from the historical  
period likewise for the future period often find a doubling of AR frequency (e.g. Lavers et al., 2013,  
Ramos et al., 2016). However, we here calculated separate 85<sup>th</sup> percentile thresholds distinctively for  
525 historical and future periods. This was done because the 85<sup>th</sup> percentile threshold as suggested by  
Lavers et al. (2012) represents the median IVT value within observed ARs during the historical period  
(Neiman et al., 2008). Consequently, the AR frequency increase found in this study is lower (as IVT  
thresholds for the future period are higher, Fig. 2) than in the aforementioned studies but still amount  
to +20-30% increase across the models.

530 Main differences to global projections arise over Norway and the Iberian Peninsula, i.e. two hotspots  
of AR impact in Europe. Over Iberia the distribution of AR related heavy precipitation is clearly  
modulated by topographic structures, like the Sistema Central Plateau, the Sierra Morena mountains,  
and the Penibaetic orogenic system. These valleys and ridges lead to zonal bands of high and low  
increases of AR precipitation over Iberia in the future. Furthermore, our regional ensemble does not  
535 indicate a robust climate change signal over Norway. Global CMIP5 models indicate for this region an  
increase of 10 to 20% in the AR contribution to heavy precipitation events in RCP8.5 (Gao et al., 2016,  
Fig. 9. therein). In contrast to this, the downscaled ensemble indicates only a weak and not robust  
response over Norway. The change in the AR percentage of annual maximum precipitation can be  
negative or positive depending on the global model and thus does not indicate a clear signal (Fig  
540 11b). Likewise, the contribution to heavy precipitation is in all regional ensemble members below 5%  
with the exception of the southwestern top of Norway (Fig 11c).

Our finding that ARs from south of 45°N have an increased presence over Europe in the future high  
emission scenario points to larger scale atmospheric circulation changes. Such change could be  
545 related to changes in the low level Jet stream (Gao et al., 2016) and/or indicate systematic changes in  
regional weather systems (Pasquier et al., 2018). At least in the southern Hemisphere a poleward shift  
of ARs has been reported for the recent decades (Ma et al., 2020). The authors suggested internal  
variations of basin scale sea surface temperatures as likely reasons.

## 6. Summary and Conclusions

550 A high resolution regional climate model with a resolution of 0.22° was applied to investigate the  
impact of ARs on Europe. The added value of regionalization was analyzed by a hindcast run to  
downscale the ERA-Interim reanalysis data set with a resolution 0.75°. The added value is most  
obvious in topographic elevated areas and in the semi arid climate zone of southern Europe (Iberia,  
555 Italy). In the central and southern part of the Iberian Peninsula the contribution to the regional  
precipitation budget is strongly modulated by E-W striking topographic signatures. This feature is not  
seen in ERA-I reanalysis data which shows on the contrary N-S striking gradients with highest  
precipitation in the west. Generally the AR imprint on analyzed indices in the ERAI data set is lower  
near the western European coasts but more visible in the distal parts of eastern Europe. This

560 indicates that ARs penetrate less far inland in the downscaled simulation compared to ERAI.

The regional climate model is further used to investigate the dynamics of ARs in present and future climate. For this in an ensemble of in total 34 simulations was carried to downscale global climate model scenarios from the CMIP5 suite with a coarse resolution between 1.4 – 3°. The models were  
565 used to downscale three greenhouse gas scenarios (RCP2.6, RCP4.5, and RCP8.5).

The historical simulations from the regional climate model ensemble are in good agreement with global ERAI reanalysis data set and an ERA-I simulation hindcast run. The regional climate ensemble shows strongest AR impact along near-coastal regions explaining up to 60% of yearly maximum  
570 precipitation rates in regions with orographic uplift (e.g. Norway). In regions with coastlines exposed to the North Atlantic but unaffected of orographic uplift AR related rain events constitute a significant contribution to the total annual yearly rain rate. Here the impact is largest in semi-arid regions of the Iberian Peninsula and along western Italy.

575 Our results show ARs become more frequent and have a higher moisture load in a future warmer climate (e.g. Lavers et al., 2013; Warner et al., 2015; Gao et al., 2016; Shields and Kiehl, 2016; Ramos et al., 2016; Shields et al., 2019; Massoud et al., 2019; Massoud et al., 2020; Whan et al., 2020). The potential of ARs to force annual maximum precipitation events increases most prominently over western France (Brittany) and northernmost Spain by up to 20% (RCP8.5). No robust ensemble  
580 response was found over Norway.

Our regional high resolution model allows a spatially more accurate calculation of AR contributions to the local water budget than possible with global earth system models. Over the Iberian Peninsula and western France the contribution of AR forced rain to the total annual precipitation increases by up to  
585 10% as well as it does with respect to the total annual precipitation that falls as heavy precipitation (up to +30%). Furthermore, the well known dryer mean climate conditions in southern Europe (e.g. Jacob et al., 2014; Kjellström et al., 2018; Gröger et al., 2021a; Christensen et al., 2021) at the end of the century favors a more important role of ARs in the future climate as AR precipitation rates increase stronger than mean precipitation rates. The increased AR contribution found for the Iberian Peninsula  
590 under contemporaneous climate drying is likely to influence the ground water recharge which is essential for maintaining ecosystem services and supporting agriculture in this area (e.g. Martos-Rosillo et al., 2015).

In particular for northern Europe we find a more southern position in the origin of ARs in the future  
595 warmer climate compared to the historical period. In turn, this likely affects the path of ARs before arriving Scandinavia as moisture travels over a longer distance over land. This leads to locally decreased precipitation rates over Norway in RCP8.5.

600 Our study clearly demonstrates a larger imprint of ARs in Europe on the regional scale and a more dominant role of forcing heavy precipitation events with potential risk for flooding under the higher greenhouse gas scenarios RCP4.5 and RCP8.5. However, under the assumption of the greenhouse gas scenario RCP2.6 most of the climate induced changes are not robust which points to the potential benefit of climate mitigation actions.

605 Finally, the present assessment of AR dynamics in regional ensembles for Europe must be  
considered as a first step since the realized horizontal resolution is still coarse (24 km) and not  
explicitly resolves convection. The future trends in regional high resolution modelling will allow  
resolutions of only a few kilometers and convection permitting models will be applied (e.g. Giorgi,  
2019; Jacob et al., 2020). This will allow a more thorough investigation of the processes mediating the  
610 response of ARs to climate change and their pathway across Europe.

#### Acknowledgements

The research presented in this study is part of the Baltic Earth program (Earth System Science for the  
Baltic Sea region, see <http://www.baltic.earth>). Regional climate scenario simulations have been  
615 conducted on the Linux clusters Krypton, Bi, Triolith and Tetralith, all operated by the National  
Supercomputer Centre in Sweden (<http://www.nsc.liu.se/>). Resources on Triolith and Tetralith were  
funded by the Swedish National Infrastructure for Computing (SNIC) (grants SNIC 002/12-25, SNIC  
2018/3-280 and SNIC 2019/3-356). The Swedish Civil Contingencies Agency (MSB) and the Swedish  
Research Council for Sustainable Development (FORMAS) have contributed funding through the  
620 HydroHazards project (MSB 2019-0651).
