7 **Abstract.** As a major sink for anthropogenic carbon, the oceans slow the increase of carbon dioxide in the
8 atmosphere and regulate climate change. Future changes in the ocean carbon sink, and its uncertainty at a global
9 and regional scale, are key to understanding the future evolution of the climate. Here we report on the changes and
10 uncertainties in the historical and future ocean carbon sink using output from the Coupled Model Intercomparison
11 Project Phase 6 (CMIP6) multimodel ensemble and compare to one observation based product. We show that the
12 ocean carbon sink is concentrated in highly active regions - 70 percent of the total sink occurs in less than 40
13 percent of the global ocean. High pattern correlations between the historical and projected future carbon sink
14 indicate that future uptake will largely continue to occur in historically important regions. We conduct a detailed
15 breakdown of the sources of uncertainty in the future carbon sink by region. Consistent with CMIP5 models,
16 scenario uncertainty dominates at the global scale, followed by model uncertainty, and then internal variability. We
17 demonstrate how the importance of internal variability increases moving to smaller spatial scales and go on to show
18 how the breakdown between scenario, model, and internal variability changes between different ocean regions,
19 governed by different processes. Using the CanESM5 large ensemble we show that internal variability changes
20 with time based on the scenario, breaking the widely employed assumption of stationarity. As with the mean sink,
21 we show that uncertainty in the future ocean carbon sink is also concentrated in the known regions of historical
22 uptake. Patterns in the signal-to-noise ratio have implications for observational detectability and time of emergence,
23 which we show to vary both in space and with scenario. We show that the largest variations in emergence time
24 across scenarios occurs in regions where ocean sink is less sensitive to forcing - outside of the highly active regions.
25 In agreement with CMIP5 studies, our results suggest that to detect changes in the ocean carbon sink as early as
26 possible, and to efficiently reduce uncertainty in future carbon uptake, modelling and observational efforts should
27 be focused in the known regions of high historical uptake, including the Northwest Atlantic and the Southern
28 Ocean.

29 1. Introduction

30 Recent increases in greenhouse gases have trapped additional heat relative to the pre-industrial era and raised
31 Earth's average temperature. Carbon dioxide (CO₂) is the primary driver of global warming in the industrial period
32 (Masson-Delmotte et al., 2021). The concentration of atmospheric CO₂ has increased from approximately 277 parts
33 per million (ppm) in 1750 (Joos et al., 2008), the beginning of the Industrial Era, to 409 ppm in 2019. However,
34 less than half of the CO₂ emitted by anthropogenic activity has remained in the atmosphere. The remaining CO₂ was
35 taken up by the natural carbon sinks of the ocean and the terrestrial biosphere. Specifically, the global ocean
36 absorbed ~26% of the total CO₂ emissions during 2011-2020 (Friedlingstein et al., 2021).

37
38 The ocean's capacity to absorb anthropogenic CO₂ is not uniformly distributed (McKinley et al., 2016, Sarmiento
39 et al., 1998). Despite increasing atmospheric CO₂ concentrations, the air-sea CO₂ flux does not change much in the
40 subtropical gyres. The regions where ocean carbon uptake notably increases are those with strong exchange
41 between the surface and the deep ocean (Ridge and McKinley, 2021; Frölicher et al., 2015; McKinley et al., 2016).
42 This response of the ocean carbon sink to increasing atmospheric CO₂ levels consists of changes in both the
43 anthropogenic and the natural carbon sink (Crisp et al. 2022, McKinley et al. 2020, Hauk et al., 2020, Gruber
44 et al. 2019, Frölicher et al., 2015). Even within regions there are large variations in the dominant mechanisms and
45 the direction of the carbon sink. In the Southern Ocean, for instance, the spatial superposition of natural and
46 anthropogenic CO₂ fluxes leads to a relatively strong uptake band between approximately 55°S and 35°S (Gruber
47 et al., 2019). However, south of the Polar Front (55°S), the different estimates agree less well (Gruber et al., 2019).
48 Supported by measurements based on biogeochemical floats (Bushinsky et al., 2019; Gray et al., 2018; Williams
49 et al., 2018), Gruber et al. (2019) argue that the region was most likely a small source in 2019.

50
51 Earth System Models (ESMs) are the primary tool for projecting the future evolution of carbon in the climate
52 system. However, quantitative projections from ESMs are subject to considerable uncertainty, particularly at
53 regional and local scales (Friedrich et al., 2012; Frölicher et al., 2014; Hauck et al., 2015; Roy et al., 2011; Tjiputra
54 et al., 2014; Terhaar et al., 2021) where less averaging is done and different individual mechanisms dominate
55 different regions. Projection uncertainty varies with lead time, spatial averaging scale, and from region to region
56 (Lovenduski et al., 2016; Schlunegger et al., 2020). For example, Lovenduski et al. (2016) showed a spatially
57 heterogeneous pattern of projection uncertainty in CO₂ flux projections over 17 ocean regions for CMIP5 models.
58 Furthermore, by comparing uncertainty at the global scale to the scale of the California Current System, they show
59 that uncertainty is higher at smaller scales. Schlunegger et al. (2020) further shows different partitioning of

60 uncertainty for 10 ocean basins at the year 2050. All said, if ESMs are to be used to quantify future changes in
61 ocean carbon uptake, especially across shorter timescales and at regional spatial scales, and to inform observational
62 campaign planning, their uncertainties must be well known and well understood (Lovenduski et al., 2016).

63
64 A systematic characterization of projection uncertainty has become possible with the advent of the Coupled Model
65 Intercomparison Project (CMIP), as a number of climate models of similar complexity provided simulations over
66 a consistent time period and with the same set of emissions scenarios (Lehner et al., 2020). There are three main
67 types of uncertainty in climate model projections, as described by Hawkins and Sutton (2009) (hereafter HS09):

68
69 **Uncertainty due to internal variability:** Internal variability is the unforced natural climate variability resulting
70 from the internal processes in the climate system. Modes such as the El Niño–Southern Oscillation, North Atlantic
71 Oscillation, Atlantic Multidecadal Oscillation, Pacific Decadal Oscillation, and Southern Annular Mode (SAM)
72 contribute to this internal variability. Internal variability also includes variability that acts on shorter time and
73 spatial scales, such as submesoscale and mesoscale ocean features (Frolicher et al., 2016). The real world follows
74 only one of an infinite possible number of *realizations* of internal variability, and due to its chaotic nature, the
75 future evolution of internal variability is not predictable beyond short timescales (Somerville, 1987; Lorenz, 1969).
76 Climate model simulations do not attempt to reproduce the exact observed evolution of internal variability, but
77 produce their own, unique realizations that aim to capture the correct statistics of this variability. Hence, our
78 analysis must account for internal variability, both when comparing historical model simulations to observations,
79 and when considering uncertainties in the future ocean carbon sink. In HS09, a fourth-order polynomial fit to
80 simulated global and regional temperature timeseries represented the forced response, while the residual from this
81 fit represented the internal variability. There is thus, an assumption of stationarity (constant in time) in their method.
82 Moreover, this approach could possibly conflate internal variability with the forced response in cases where low-
83 frequency (decadal-to-multidecadal) internal variability exists, or when the forced signal is weak, which makes the
84 statistical fit a poor estimate of the forced response (Kumar and Ganguly, 2018). In this study, we instead use a
85 Single-Model Initial-condition Large Ensemble (SMILE) to robustly quantify the internal variability across time
86 and scenarios using ensemble statistics (Lehner et al., 2020). A SMILE is an ensemble of model realizations that
87 each starts from different initial conditions but uses the same model and forcing, and provides representations of
88 the climate system that are equivalent except for internal variability.

89 **Uncertainty due to model structure:** Models differ in their resolution, structure, numerics, and parameterization
90 of processes. These differences cause models to respond differently to the same forcing. For example, the CMIP5

91 model simulations run under Representative Concentration Pathway 8.5 (RCP8.5) project a wide range of
92 cumulative anthropogenic carbon storage by 2100 (320–635 Pg-C) (Ciais and Sabine, 2013) due to both internal
93 variability and model uncertainty (Lovenduski et al., 2016).

94 **Uncertainty due to emission scenario:** The future of the climate system depends on human activity and our
95 emission of climate active gases that change radiative forcing. Future emissions are highly uncertain, given our
96 inability to project the complex changes in society and technology upon which they depend. As a result, future
97 simulations are run with a range of possible “scenarios” for how future emissions (or atmospheric concentrations)
98 will evolve under different socioeconomic storylines. These scenarios are prescribed via the internationally
99 coordinated experiments organized by the Coupled Model Intercomparison Project. Since the future emission
100 trajectory is unknown, these future simulations are referred to as projections, rather than predictions. Projections
101 of future ocean carbon uptake from ESMs are greatly influenced by the choice of emission scenario (Lovenduski
102 et al., 2016). For example, cumulative ocean carbon uptake from 1850 is projected to saturate at approximately 290
103 ± 30 GtC under ssp126, and to reach 520 ± 40 GtC by 2100 under ssp585 for CMIP6 models (Canadell et al.,
104 2021).

105 Together with the patterns of changes in the sink, the patterns of internal variability allow for an assessment of the
106 required timescales for detection of changes in the ocean carbon sink. Detection means that we can robustly separate
107 the forced signal from internal variability (McKinley et al., 2016). Detectability can be assessed using Time of
108 Emergence (TOE; Hawkins and Sutton, 2012; Lovenduski et al., 2016; McKinley et al., 2016; Rodgers et al., 2015;
109 Schlunegger et al., 2020 & 2019). For example, McKinley et al. (2016) and Schlunegger et al. (2019) showed that
110 the forced signal of increasing ocean carbon uptake is not detectable in the Ekman convergence regions of the
111 subtropical gyres. Schlunegger et al. (2020) builds on that using four large ensembles of CMIP5 ESM simulations
112 with two forcing scenarios to show that air-sea CO₂ flux TOEs show strong agreement between the large-ensembles
113 not just for global and regional scales but also locally and spatially. Their use of only four models and two scenarios
114 however, potentially underestimates the contribution of model and scenario uncertainty.

115

116 Here, we build on previous work using CMIP6 models. We make use of an ensemble of 13 models to better capture
117 model uncertainty in the response to different forcing (scenarios) and three scenarios to represent a wider range of
118 future possibilities including a strong mitigation scenario. We start by analysing the regional patterns of historical
119 ocean carbon uptake and how they are projected to change in the future (Sect. 3.1). We estimate internal variability
120 from a comprehensive SMILE, avoiding the stationarity assumption common in previous work, which we show is

121 violated. Then, we examine the partitioning among different sources of uncertainty (Sect. 3.2) and provide a novel
122 analysis of how the three sources of variability change across the full continuum of scales (Sect. 3.3). Having
123 Shown how the uncertainty and distribution among sources differ based on scale of integration and region of
124 interest, we analyse local patterns of uncertainty by the source (Sect. 3.4). The final section explores the
125 detectability of the model projected signal given the uncertainty imposed by internal variability. We report on the
126 scenario-dependent Time of Emergence, using a scenario specific measure of internal variability in order to make
127 useful suggestions for future observations.

128
129

130 **2.Data and Methods**

131 2.1 Model Data Selection

132 Here we use results from models selected from the 6th Coupled Model Intercomparison Project (CMIP6; Eyring
133 et al., 2016). Models are chosen based on availability, meaning all models that provided at least one realisation
134 for air-sea CO₂ flux (fgco2) for the CO₂ concentration driven experiments of interest. One realization of each
135 model over the historical period and three scenarios that represent the low (ssp126), mid (ssp245), and high
136 (ssp585) ranges of future atmospheric CO₂ concentrations are analysed. A total of 16 models met these criteria,
137 out of which 3 were excluded as outliers (see section S1 in the Supplements). To maintain equal sampling, only
138 one realization of each model was selected, except when specifically using the large ensembles to assess internal
139 variability. Finally, since the ocean component of the models may be on different grids, all model data were
140 remapped to a regular one-by-one-degree grid and a 10 year running mean filter was applied to the time-series.
141 We did not account for potential drift in the models. However, the drift is known to be small in the models
142 compared to the historical trends for CMIP5 models (Hauck et al, 2020). For 11 of our CMIP6 models for which
143 piControl runs are available, on average, the drift is more than one order of magnitude smaller than the change in
144 the model scenario with the smallest trend over the 21st century, on the global scale.

145

146 2.2 Sources of uncertainty

147 Total uncertainty is composed of internal, model, and scenario uncertainty in equation 1, which assumes that each
148 of these sources is independent. Here, each source of uncertainty is considered as a function of time (t) and location
149 (l) (Lovenduski et al., 2016):

150

$$U_T^2(t, l) = U_I^2(t, l) + U_M^2(t, l) + U_S^2(t, l)$$

where $U_T(t, l)$ is total uncertainty, $U_I(t, l)$ is internal variability, $U_M(t, l)$ is model uncertainty, and $U_S(t, l)$ is scenario uncertainty. The fractional uncertainties for each source are calculated as $\frac{U_I^2}{U_T^2}$, $\frac{U_M^2}{U_T^2}$, and $\frac{U_S^2}{U_T^2}$ (Lovenduski et al., 2016).

HS09 assume $U_I(t, l)$ to be constant in time (stationary) and use a 4th degree polynomial fit to measure internal variability as the spread over time and scenario of the residuals for each model's signal relative to the fitted signal. We show in the Supplements (see section S2) that internal variability depends on time and scenario, violating the commonly used assumption of stationarity. Using a SMILE allows us to account for these variations without having to make any assumptions about distribution or stationarity of variability (Frolicher et al., 2015; Schlunegger et al., 2020). Here we estimate internal variability as two times the standard deviation of the annual carbon sink across 50 realizations from a Single Model Initial Condition Large-ensemble based on CanESM5 (Eq. 2):

$$U_I(t, l) = 2 \sqrt{\frac{1}{N_S} \sum_{s=1}^{N_S} \text{Var}(\text{CanESM5 Large Ensemble})} \quad (2)$$

where s indicates each scenario (N_S is the number of scenarios) and Var indicates the variance over the large ensemble of CanESM5. In the CanESM5 SMILE, each realization starts from different initial conditions which are drawn from points separated by 50 years in the piControl simulation. Thus, the spread across the realizations gives a robust estimate of the internal variability, including sampling over longer term ocean variability.

Previous studies have also used SMILEs to estimate variability (Frolicher et al., 2015; Schlunegger et al., 2020), although they used either a limited ensemble size or single scenario. We show in the Supplements (Fig. S2), that a sufficiently large ensemble size is needed to capture internal variability, and that internal variability depends on the scenario. In the ideal case, if every CMIP model provided sufficiently large SMILEs for each scenario, an ensemble mean estimate of the variability could be obtained and would represent a best estimate (but still possibly biased compared to the real world). However, only a handful of CMIP6 models produced multiple ensemble members.

179 We selected the CanESM5 SMILE as it is the only model that has a large enough ensemble over the entire timeline
180 and set of experiments to make estimate internal variability robustly and across scenarios.

181
182 The use of a single model to estimate the scale of internal variability leads to some uncertainty in our estimates, as
183 models do not agree perfectly with each other on the variability. Nonetheless, over the historical period, variability
184 between large ensembles from three models that have enough ensemble members is within 10%, on the global scale
185 (Fig S3). Differences will be larger at smaller scales; however, the general patterns of the magnitude of internal
186 variability (see Fig. S4) are in good agreement across models and are consistent with known regions of high
187 variability in the observed ocean, validating our use of the CanESM5 SMILE

188
189 Model uncertainty is calculated by taking the variance across the forced signal of all available models for each
190 scenario, averaging over the three scenarios, and then reporting twice the square root of the result (Eq. 3).

$$191 \quad U_M(t, l) = 2 \sqrt{\frac{1}{N_S} \sum_{s=1}^{N_S} \text{Var}_m(F(m, s, t, l))} \quad (3)$$

192 where Var_m means the variance taken across different models for individual times and scenarios, m indicates each
193 model, and t stands for time. $F(m, s, t, l)$ is the forced signal and can be related to each realization as follows:

$$194 \quad T(m, s, t, l) = F(m, s, t, l) + R(m, s, t, l) \quad (4)$$

195
196
197 Where, $T(m, s, t, l)$ represents the reported output, i.e. each realization, but must be corrected for internal
198 variability. $R(m, s, t, l)$ is the residual from the forced signal caused by internal variability. Here, the variance in
199 the forced signal across all models is calculated by correcting the total variance across all models' one realization
200 for the variance caused by internal variability. The corrections are done by subtracting the variance across the same
201 number of CanESM5 ensemble members as the multi-model ensemble (13 members) from the variance across the
202 one realization of all of the 13 models. For this correction only, the sample sizes (13) are kept the same so that the
203 internal variability removed from the variance across the models' first realizations is not overestimated by a well
204 sampled 50-member ensemble (see section S3 in the Supplements).

205
206 $U_s(t, l)$ is the scenario uncertainty. Scenario uncertainty is measured as twice the standard deviation (square root
207 of variance) across scenarios of the multi-model mean signal (Eq. 5).

208

209

$$U_S(t, l) = 2 \sqrt{\text{Var}_m \left(\frac{1}{N_m} \sum_{m=1}^{N_m} T(m, s, t, l) \right)} \quad (5)$$

210

211

212

213

214

215

216

217

218

where N_m is the number of models. The multi-model mean across the first realizations of the 13 models gives the multi-model forced response and does not require correction for internal variability as done for model uncertainty before.

214

215

216

We conduct analysis on three different scales: single grid point (one-degree resolution), regional, and global. When regional and global analysis is done, the dependence on location is taken away by averaging over that region or the whole global ocean.

217

218

2.3 Time of Emergence (TOE)

219

220

221

222

223

224

225

In order to know when the forced response is distinguishable from internal variability, TOE is calculated following the approach of McKinley et al. (2016). The time of emergence is the first year when the multi-model mean anomaly is larger than internal variability – approximated by two times the standard deviation across the 50 member CanESM5 ensemble - for five consecutive years (the first year of this five-year period is reported as the time of emergence). The result is reported at each grid point for the 10-year running mean smoothed anomaly relative to the 1995-2015 mean (detection of a change relative to the current state of the ocean).

226

2.4 Scale Dependence

227

228

229

230

231

232

Finally, the scale dependence of the sources of uncertainty is measured at year 2050 using ssp245 for internal variability and model uncertainty, and using all scenarios for scenario uncertainty. The analysis is done by moving a sliding sample window of a given area across the earth, and then repeating with a larger and larger window until all scales from $<100 \text{ km}^2$ to the whole Earth are considered. For each source of uncertainty and averaging scale, the average for all rectangles across the globe is reported, where each rectangle contains the same ocean area.

233 3. Results and Discussion

234 3.1 Global Analysis

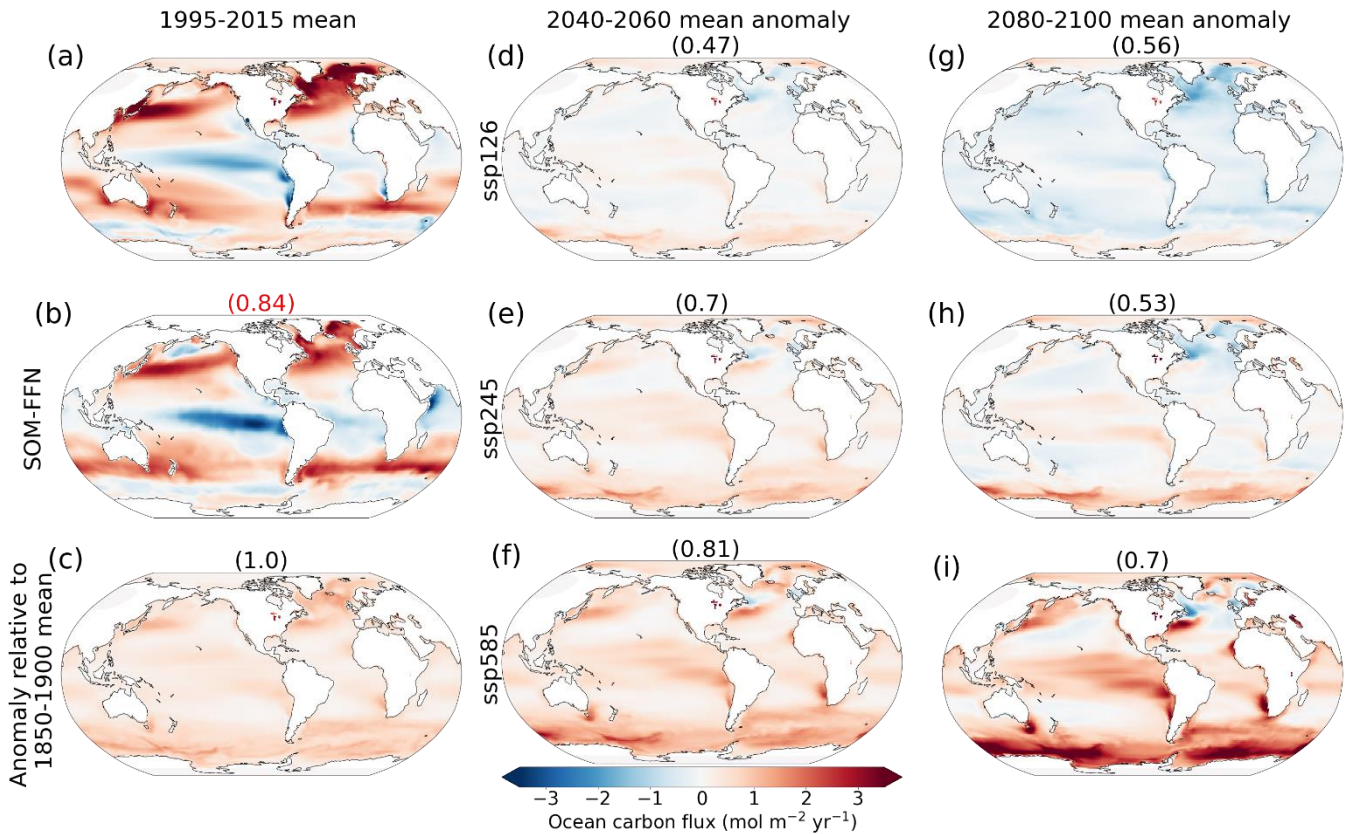

235 The pattern of the carbon sink in the CMIP6 multi-model ensemble mean from the historical experiment over 1995-
236 2015 matches that of the Landschützer (2016) Self Organizing Map - Feed Forward Neural Network (SOM-FFN)
237 observation-based data product estimate (correlation coefficient of 0.84, compare Figs. 1a and 1b). We use the
238 multi-model mean response to external forcing as a more robust estimate of the forced climate signal than the
239 response of any single model (Tebaldi & Knutti, 2007). Unlike in ESMs, the observation-based product only
240 represents the one realization of the real world, which includes internal variation, and is therefore not directly
241 equivalent to the forced signal. However, the comparison to the 20 year mean multi-model mean still informs us
242 about the degree of agreement between the two products. When compared to the observation-based data product,
243 the CMIP6 multi-model mean shows a larger sink (positive flux) in the North Atlantic and North and North-West
244 Pacific but a smaller sink in the Southern Ocean (Fig 1a, b). Additionally, the observation-based data product shows
245 a larger source in the Equatorial Pacific and Indian Ocean than the CMIP6 multi-model ensemble.

246
247 While most of the global ocean shows a net sink relative to the pre-industrial era, the largest change takes place in
248 some highly active regions such as the subpolar North Atlantic, Southern Ocean, Eastern Equatorial Pacific, and
249 western boundary currents of the mid-latitude gyre systems in the Pacific and Atlantic Oceans (Fig. 1c). These
250 regions of largest change in the carbon sink (anthropogenic plus changes in the natural carbon sink) are the regions
251 where there is a surface-depth connectivity as the air-sea flux of anthropogenic carbon is fundamentally limited by
252 the rate of surface-to-depth transport (Graven et al., 2012; Ridge and McKinley 2021). These results for CMIP6
253 models are consistent with those for CMIP5 models shown by McKinley et al. (2016) and earlier studies such as
254 Sarmiento et al. (1998). Here, we provide a new metric for quantifying these highly active regions. We find that
255 for all three scenarios and both mid-21st century (2040-2060 mean) and late- 21st century (2080-2100 mean) time
256 periods (with the exception of ssp126 late-century where strong mitigation of anthropogenic CO₂ emissions results
257 in broad patterns of negative anomalies), approximately 70% of the changes in the sink relative to the preindustrial
258 area takes place in less than 40% of the global ocean (see Supplement Fig. S7 and section S5).

259
260 The regions of largest future carbon uptake, relative to the 1995-2015 mean, are within the same highly active
261 regions responsible for most of the uptake over the historical period. The correlation coefficients at the top of each
262 panel in Fig. 1 (except 1b) represent the pattern correlation between future absolute anomalies, relative to 1995-
263 2015, and anomalies in 1995-2015, relative to the pre-industrial era. The high correlations indicate that regions that

264 have been most active in carbon sequestration since the pre-industrial era are the same regions that will continue
 265 to change most into the future, particularly with larger increases in atmospheric CO₂ (ssp585). Our results support
 266 the findings of Wang et al. (2016) who showed that projected future air-sea CO₂ fluxes are strongly associated with
 267 simulated historical air-sea CO₂ fluxes. This confirms that the historical state is a good predictor for the future state
 268 (Wang et al., 2016) not only in terms of magnitudes of the sink, but also in the spatial pattern.

269
 270
 271

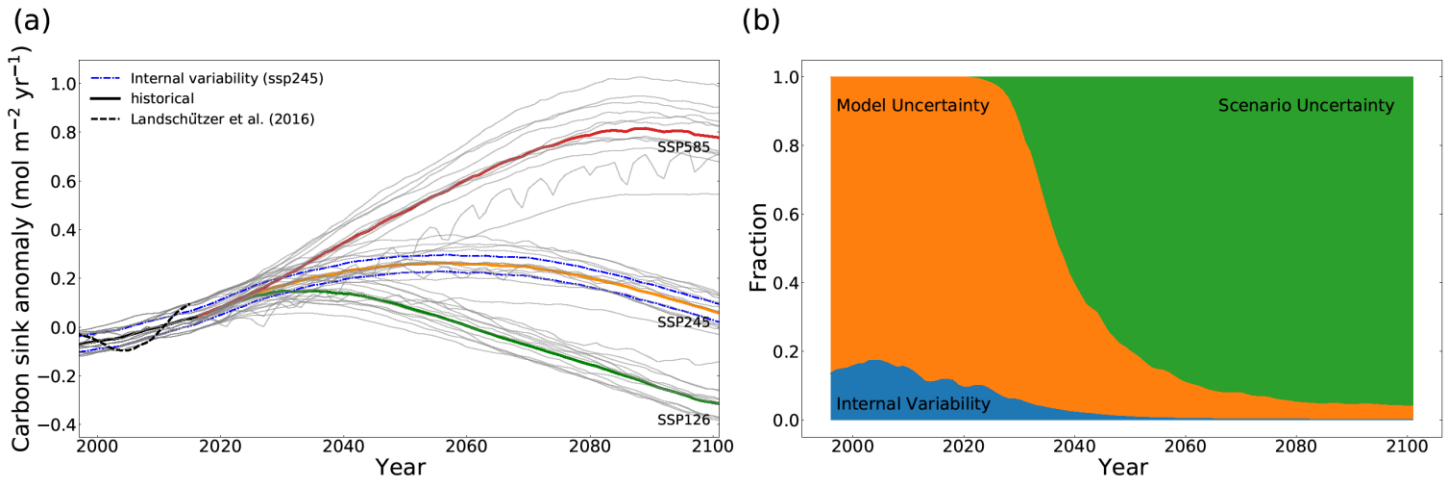

272

273 **Figure 1-** CMIP6 multi-model mean maps of carbon sink and sink anomalies using one realization of each model. Columns
 274 represent different time periods, being the recent time (1995-2015 mean), mid-century (2040-2060 mean), and late-century
 275 (2080-2100 mean). Note: the sink is positive into the ocean. The first column shows (a) the CMIP6 ensemble mean air-sea
 276 CO₂ flux over 1995-2015, (b) Landschützer et al. (2016) SOM- FFN product, and (c) the CMIP6 ensemble mean flux
 277 anomaly relative to the 1850-1900 mean. Other panels are anomalies relative to the 1995-2015 multi-model mean (panel a).
 278 Panels d through i show different scenarios. Numbers above each map are correlation coefficients between the absolute value

279 of the change relative to 1995-2015 with the 1995-2015 anomaly map relative to the pre-industrial era in panel c, except the
280 red number at the top of panel b that is the correlation coefficient with this panel and panel a.
281

282 The multi-model mean sink anomalies for two future periods, 2040-2060 and 2080-2100, show how the sink is
283 projected to evolve, relative to 1995-2015, according to time and choice of emission scenario (Fig. 1d-i). The
284 regional patterns show mostly positive anomalies at mid-century with largest changes in the higher emission
285 scenarios (ssp585). Towards the end of the century, however, broader patterns of negative anomalies are expected
286 in ssp126, as emissions turn negative in the late-century in this scenario. The largest absolute values of anomalies
287 are still within the same highly active regions discussed before with surface-depth connectivity regardless of it
288 being positive or negative. The late-century anomalies are predominantly positive in ssp585 which corresponds to
289 the highest emission scenario (continuing to grow larger compared to the mid-century), while ssp245 is somewhere
290 in between, with regions of positive and negative anomalies. Under ssp245, as CO₂ emissions decrease and
291 atmospheric CO₂ start to level off, the intensity of uptake decreases in the midlatitude western boundary currents
292 and subpolar North Atlantic in the late-century, and anomalies in the Eastern Equatorial Pacific also decrease,
293 compared to the mid-century. The globally integrated ocean carbon uptake rates are summarized in Table 1.
294

295
296 **Figure 2-** (a) Thick lines are multi-model means of the global mean ocean carbon sink anomaly timeseries relative to 1995-
297 2015. Individual models are plotted as thin grey lines in the background. The black dashed line shows the Landschützer et
298 al. (2016) SOM-FFN product. Both models and SOM-FFN timeseries are smoothed with a 10-year running mean. The blue
299 dashed lines show internal variability for ssp245. (b) Timeseries showing the breakdown of uncertainty to different sources
300 with time for the global ocean carbon sink anomaly. The internal and model uncertainty are averaged for different scenarios.

Table 1- CMIP6 multi-model mean globally averaged carbon sink anomalies (with ranges within the 20-yr period in parentheses) relative to the 1995-2015 mean (in mol-C m⁻² yr⁻¹) and internal variability from CanESM5 (with model uncertainty in parentheses) for the globally averaged ocean carbon sink anomalies for the three scenarios and the average values across scenarios.

317 The trends in the global mean ocean carbon sink anomalies over 1995-2015 are statistically consistent between the
318 CMIP6 multi-model ensemble mean and the Landschützer et al. (2016) observation-based data product (Fig. 2-a),
319 based on the test from Santer et al. (2008; see Supplements section S5). However, the SOM-FFN based time-series
320 shows a larger multi-decadal variability (variations in the 10-year running mean timeseries on top of the trend) than
321 seen in individual model realizations, and is larger than the range of internal variability estimated from the
322 CanESM5 SMILE. The difference could be due to either overestimation of internal variability by the SOM-FFN
323 method, or underestimation of the internal variability from the ESMs. Given that on regional scales the SOM-FFN
324 data is within the range of internal variability projected by the CMIP6 large-ensemble of CanESM5 (see Sect. 3.3),
325 and that there are significant gaps in the spatial and temporal sampling that underlies the Landschützer et al. (2016)
326 estimate, it seems plausible that the discrepancy is largely due to overestimation of internal variability on the global
327 scale by the SOM-FFN technique. This is consistent with the findings of Gloege et al. (2021), which showed that,
328 globally, the magnitude of decadal variability is overestimated by 21% by the SOM-FFN technique, attributed to
329 the amount of data filling.

330
331 On the global scale, model uncertainty is the dominant source of uncertainty in the historical period, but scenario
332 uncertainty comes to dominate later (Fig. 2b). Over the 1995-2020 period, model uncertainty explains around 85%
333 of the total uncertainty. Scenario uncertainty becomes the dominant source after 2040, explaining almost 40% of
334 the total uncertainty at that time and more than 90% by the end of the century. Internal variability explains 15% at
335 the start of the century but only around 1% by the end. It is worth mentioning that the decreased share of uncertainty
336 associated with model and internal variability do not mean that model or internal variability decrease in an absolute
337 sense; rather, their importance relative to scenario uncertainty declines. These results regarding the importance of
338 model and scenario uncertainties for multidecadal projections, and dominance of scenario uncertainty with time
339 agree with previous studies using CMIP5 models (Lovenduski et al., 2016; Schlunegger et al., 2020).

340
341 Absolute internal and model uncertainty of the global carbon sink change with time, based on the scenario (Table
342 2, Fig. S3). High emission scenarios such as ssp585 show a larger change for both internal and model uncertainty
343 where the forcing is stronger (Fig. S3). When averaged for the three scenarios, a constant increase in the magnitudes
344 of both model and internal variability is seen through the century until 2080-2100 when the values either do not
345 change or decrease slightly (Table 1). Model uncertainty more than doubles towards the end of the century
346 compared to 1995-2015 on average for different scenarios. This is consistent with Lovenduski et al. (2016) who
347 argues that the increase is due to difference in climate sensitivities between models that manifest more strongly
348 with time (and hence cumulative emissions). Additionally, the dependence of internal variability on the scenario is

349 an interesting result. Future SMILEs from multiple models will allow evaluation of the degree of dependence and
350 the driving mechanisms of such changes with time based on the forcing (scenario). Our result of internal variability
351 dependence on scenario implies that the time of emergence of a signal out of internal variability will be affected
352 by changes in the internal variability under different future forcing scenarios – which we return to in Section 3.4.

353

354 3.2 Dependence of the sources of uncertainty on spatial scale

355 It is generally accepted that uncertainty and, most importantly, internal variability grow larger as the averaging
356 (integration) scale gets finer, because on larger scales the variability is averaged out. Here, we provide a novel and
357 continuous view of change in variability across scales from the global to grid scale, by measuring how variability
358 changes relative to scale on average (Fig. 3). At the global scale, the dominant source of uncertainty is scenario
359 uncertainty, followed by model and internal variability respectively, consistent with Fig. 2b. However, as the
360 averaging (integration) scale gets finer, model and internal variability grow rapidly, while scenario uncertainty only
361 grows slightly on average (over all regions of this size). At an averaging (integration) scale with an area finer than
362 75 million km² (on average around the globe), model uncertainty becomes the dominant source of uncertainty, and
363 at a scale finer than 3 million km², internal variability becomes larger than scenario uncertainty. The idea of scale
364 dependence of these uncertainties was tested in Lovenduski et al. (2016) by comparing an area covering the
365 California Current System with the global ocean. Here, we provide a novel analysis on a continuum of scales
366 covering global to regional to local scales. While the results here hold true on average over the globe, scale
367 dependence is partially controlled by the particular region being sampled. Finally, while our estimates of the
368 magnitudes of sources of uncertainty and the cross over points at which the dominance of internal variability over
369 model uncertainty and model uncertainty over scenario uncertainty takes place, depend on the choice of ESMs and
370 the method for calculation of internal variability, the general patterns are unlikely to be model dependent.

371

372

373

374

Figure 3- Sources of uncertainty versus area of averaging. Internal variability is based on ssp245 year 2050 of all CanESM5 members. Scenario uncertainty is based on all scenarios of the 13 models at year 2050 and model uncertainty is the corrected standard deviation of our 13 models at year 2050 of ssp245. The values of uncertainties are averaged over all different rectangular areas of each size that can scan the globe. Dashed lines indicate the size of the averaging window and not a specific location.

377

378

379

380

381

3.3 Regional Analysis

382

We further expand on the findings of our analysis of the scale dependence of uncertainty averaged over the globe by repeating the uncertainty breakdown for two specific regions: one between 40°- 60° N in the Northeast Pacific (NE Pacific) between 130°- 160° W and one in the Northwest Atlantic (NW Atlantic) between 40°- 70° W at the same latitude. We chose these regions, first, to be of the similar size, and second to represent very different carbon dynamics. The NW Atlantic region represents a highly active region while the NE Pacific region is more typical of quiescent ocean regions, where the flux anomalies are relatively small.

383

384

385

386

The variation across scenarios is at all times smaller than internal variability in the NE Pacific (Fig. 4a). This suggests both that it will be difficult to robustly detect any human induced changes in observations of the NEP carbon sink, and that potential future differences relating to choice of mitigation scenarios will not be readily

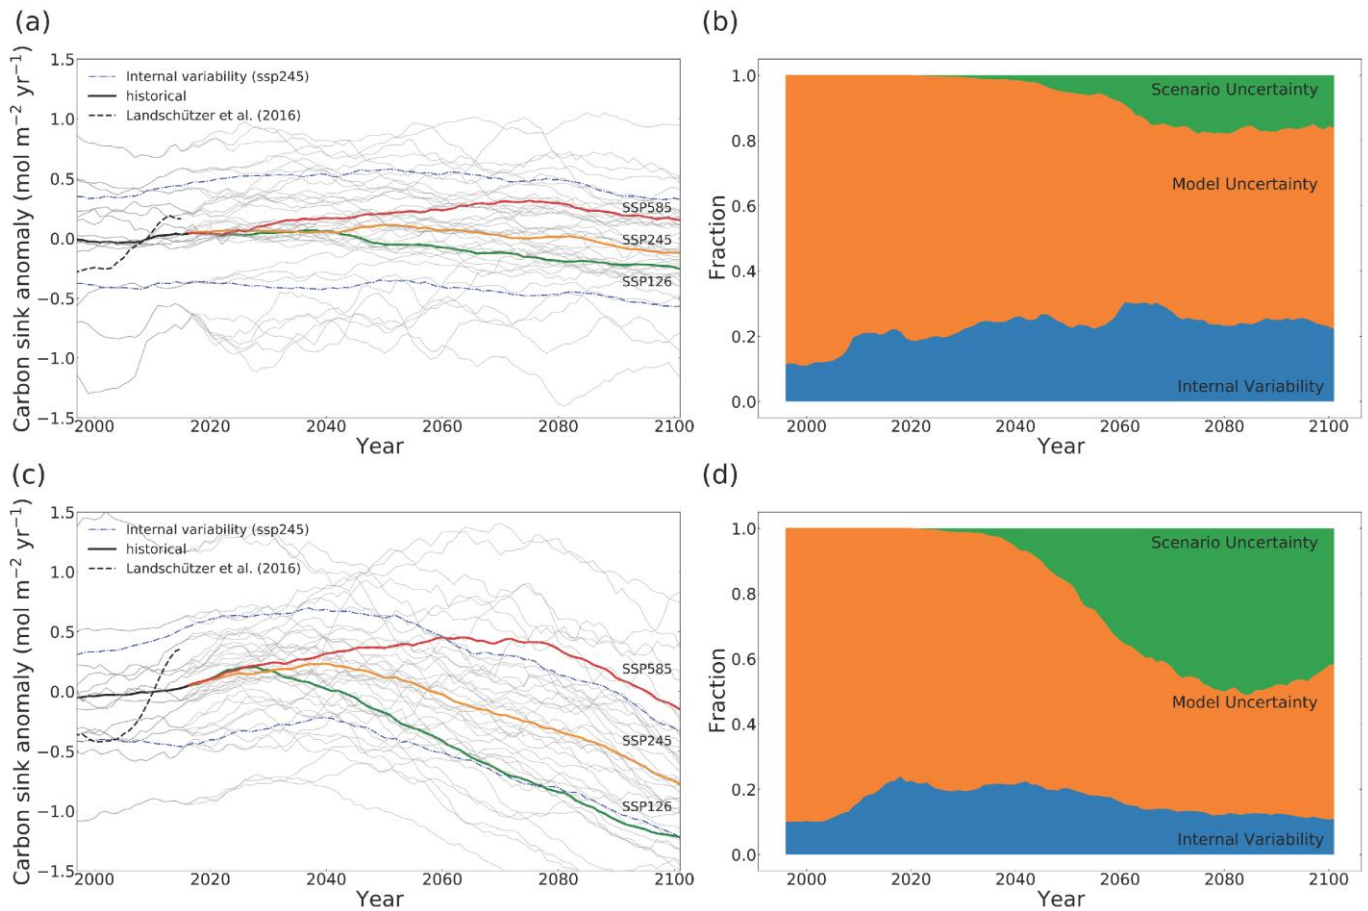

387

392 apparent in the NE Pacific carbon flux. This is true even for the high emission scenarios, because the anomalies
393 are small regardless of scenario (Table 2). We speculate that in the absence of mechanisms providing a pathway
394 to the depth where significant CO₂ accumulation occurs, the surface pCO₂ trend will follow that of the
395 atmosphere closely, causing ΔpCO₂ and therefore air-sea carbon flux to remain fairly constant for all scenarios. In
396 the NW Atlantic however, the deviation across scenarios becomes larger than the internal variability in the early
397 2060s (Fig. 4c). The response of the region to climate change is dependent on the scenario (Table 2), or, in other
398 words, the amount of carbon dioxide in the atmosphere. This is because the NW Atlantic is a highly active region
399 where the air-sea flux actively responds to the atmospheric CO₂ concentration. The connection to depth allows
400 for surface water to be replaced with water masses whose pCO₂ trend lags behind that of atmosphere. The trend
401 of the CMIP6 multi-model time-series over the historical period is statistically consistent (See Supplements
402 section S5) with that of the observation-based SOM-FFN product, and the multi-decadal variability is within the
403 range of internal variability measured by the CanESM5 large-ensemble in both regions. We note that both of
404 these regions are relatively well sampled, which may lead to more robust estimates of multi-decadal variability in
405 the Landschützer et al. (2016) dataset, and better agreement with the models than seen at the global scale.
406

407 Fractional estimates of each source of uncertainty vary with time and have different patterns for these two regions.
408 Internal variability and model uncertainty in the NE Pacific and NW Atlantic are larger by an order of magnitude
409 than at the global scale (Table 2). A lesser importance for scenario uncertainty and greater importance for internal
410 and model uncertainty is apparent in both regions compared to the global scale, in agreement with Schlunegger et
411 al. (2020). Over the period 1995-2020, model uncertainty is the dominant source of uncertainty in both the NE
412 Pacific and NW Atlantic (80-90%), while the remainder is internal variability (Fig. 4bd). Internal variability
413 explains around 25-30% of the total uncertainty in the NE Pacific throughout the century. In the NW Atlantic
414 however, its share drops to 15% by the end of the century. The share attributable to internal variability is much
415 larger during the 21st century in both regions compared to the global scale. Internal variability is larger in the NW
416 Atlantic in an absolute sense (Table 2), but its share of the total uncertainty is larger in NE Pacific (Fig. 4b). The
417 large share of internal variability in NW Pacific indicates the need for sustained observations in the region. Overall,
418 internal variability averaged over the scenarios shows a small increase, but no clear trend in time in both regions
419 until the 2080-2100 period where it decreases, consistent with the global estimates (Table 2). We showed earlier
420 that in the NE Pacific scenarios do not differ because the region is a highly active region (Fig. S7) - scenario
421 uncertainty explains less than 20% of the total uncertainty at the end of the century in the NE Pacific. In the NW
422 Atlantic, scenario uncertainty grows larger with time, becoming 45-50% of total uncertainty by the end of the
423 century. In both regions, model uncertainty is the dominant source of uncertainty in all years.

Our regional analysis confirms that while uncertainty and its distribution among sources depends on the spatial scale of integration, the specific location also matters (Lovenduski et al, 2016; Schlunegger et al., 2020). Schlunegger et al., (2020) tested this idea for 10 ocean basins but with different sizes (see their Figure 9). We focused on keeping the sizes similar and analyse a highly active region versus a more quiescent ocean region. The key message here that there is an association with the importance as well as the magnitude of sources of uncertainty with how active the region is in regards to the carbon sink is not sensitive to the use of CanESM5 for estimation of internal variability. Local patterns of uncertainty broken down by source are thus needed to clarify changes based on location.

445
 446 **Figure 4-** (a), (c) Thick lines are multi-model mean timeseries of anomalies relative to the 1995-2015 mean. All model time-
 447 series averaged for the means are plotted in grey lines in the background. The black dashed line shows the Landschützer et
 448 al. (2016) SOM-FFN product. The blue dashed line shows the internal variability measured as two times the standard
 449 deviation across all 50 members of CanESM5 only for ssp245 here. (b), (d) time-series showing the breakdown of
 450 uncertainty to different sources with time. The internal and model uncertainty are averaged for different scenarios. (a), (b)

460 **Table 2-** CMIP6 multi-model mean sink anomalies (with ranges in parentheses) relative to 1995-2015 mean (in mol-C m⁻²
461 yr⁻¹) and internal variability (with model uncertainty in parentheses) for the three scenarios and their average values in NE
462 Pacific and NW Atlantic.

463

464 Consistent with the sink anomaly maps (Fig. 1), the regions that show highest uncertainty for any of the sources in
465 the future, are the same regions that show the largest uncertainties in the historical period (Fig. 5). More
466 importantly, the regions of largest future uptake uncertainty are highly correlated with the historical regions of
467 largest uptake, as shown by the pattern correlation coefficients above each panel. This is a highly significant
468 finding, because it suggests that knowledge of the regions of modern day surface carbon flux anomaly provides us
469 with information about regions of future uptake uncertainty.

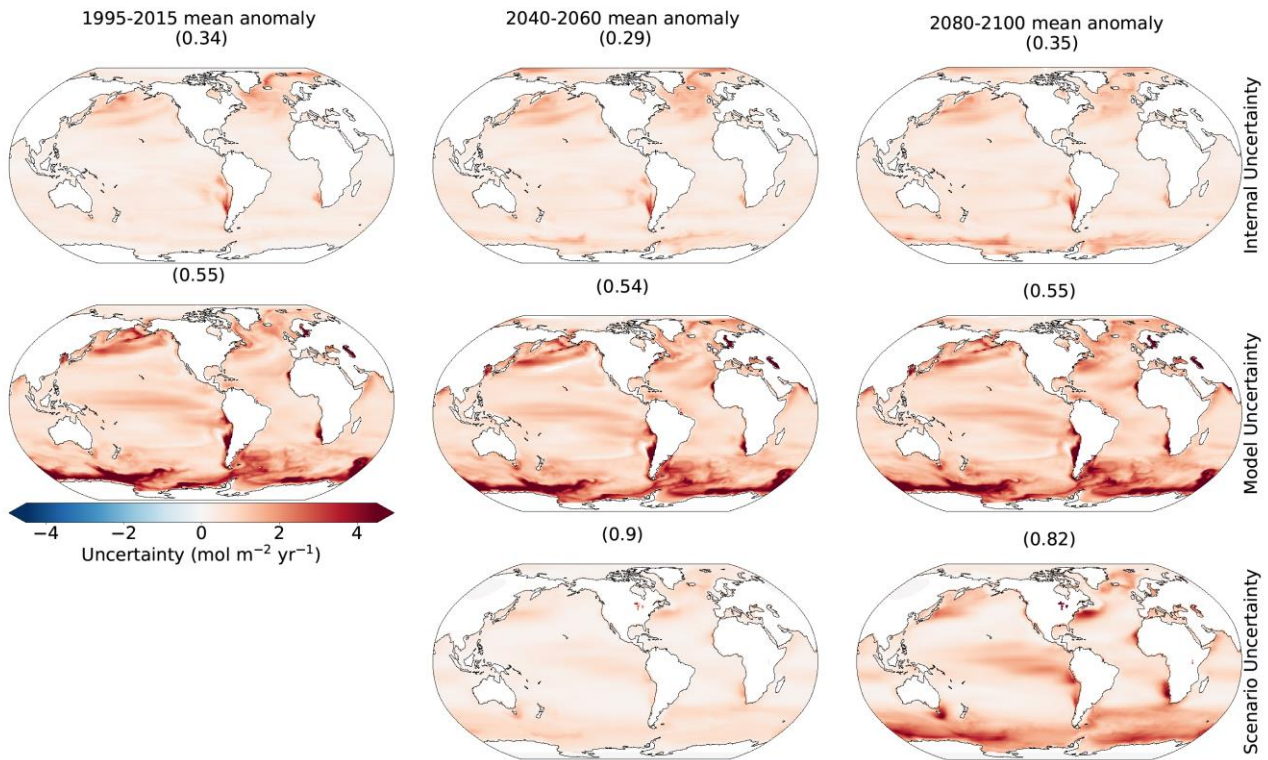

470 Internal variability from CanESM5 is most dominant in mid-latitude eastern boundary upwelling regions and
471 their extensions, in the North Atlantic, in the western boundary currents of the Gulf Stream and Kuroshio and
472 their extensions, and in the Southern Ocean (Fig. 5). There is wide agreement between different models and
473 estimation methods in regions of largest internal variability (Fig. S4). The regions of large internal variability are
474 correlated with the same highly active regions for the sink anomalies discussed earlier (Fig 1c). However,
475 correlation coefficients between internal variability and historical uptake are lower than those seen for scenario
476 and model uncertainty. An increase in internal variability with time is seen mostly in the Southern Ocean, the
477 Arctic Ocean, and boundaries of the gyre systems, while the rest of the ocean does not show a clear change. The
478 maps in Figure 5 are averaged over the three scenarios, which masks the changes to some extent. However, we
479 show in the Supplements (see section S2) that changes in the globally averaged internal variability with time are
480 different for different scenarios.

481 Model uncertainty is consistently highest in the highly active regions (Figure S7), leading to strong correlation
482 with the anomaly maps of Fig. 1c. In these regions, ocean circulation impacts surface pCO₂ through advection
483 and water mass transformation regionally (Bopp et al., 2015; Toyama et al., 2017) and models have substantial
484 differences in ocean circulation. Ridge and McKinley (2021) suggest that while global surface carbon fluxes and
485 carbon storage are largely similar across ESMs over the historical period, consistent with the external forcing
486 from atmospheric pCO₂ growth being the main driver of the historical sink (McKinley et al., 2020), uncertainties
487 in ocean circulation may become important in the future under a changing trajectory of atmospheric boundary
488 conditions. The model uncertainty is largest in the Southern Ocean consistent with CMIP5 models (Frölicher et
489 al., 2015). Here, mode and intermediate waters are formed, and the complex nature of the sink varies on all time
490 scales (Gruber et al. 2019). Frölicher et al. (2015) note the largest disagreement in ocean carbon uptake between

491 models is in the Southern Ocean because the exact processes governing heat and carbon uptake remain poorly
492 understood. The importance of model uncertainty in the Southern Ocean provides a clear focal point for
493 modelling centers to concentrate their efforts in reducing projection uncertainty.

494 Scenario uncertainty exhibits the largest change with time. This is by construction as the scenarios deviate from
495 each other with time to represent a range of pathways for future socio-economic possibilities in order to assess
496 the long-term impacts of short-term decisions (Riahi et al., 2017). Importantly, the correlation coefficients are
497 highest between scenario uncertainty and the current sink regions, indicating that the same highly active regions
498 are the regions that show the largest divergence among scenarios, and that the sink in most other regions does not
499 respond as strongly to scenario differences. We showed an example of this earlier, where the timeseries of the
500 multi-model signals for the three scenarios did not emerge out of internal variability in the NE Pacific by 2100,
501 whereas they did for the highly active region of the NW Atlantic. This shows that with pCO₂ differences across
502 the air-sea interface being the main driver of the sink (Fay & McKinley, 2013; Landschützer et al., 2015;
503 Lovenduski et al., 2007; Mckinley et al, 2020; McKinley et al., 2017), the sink in these active regions evolves as
504 the atmospheric CO₂ concentration changes because ocean processes associated with surface-depth connectivity
505 constantly keep the surface ocean pCO₂ out of equilibrium with the atmosphere. In other words, the surface water
506 in these regions are constantly renewed, mostly through advection and water mass formation, with water masses
507 whose pCO₂ has not increased at the same rate as the atmosphere. Elsewhere, these conditions do not hold true
508 and water at the surface equilibrates with the atmosphere on shorter time scales, decreasing the sensitivity to the
509 projection scenario. These uncertainties are central to the ability to detect human induced trends in observations
510 of the surface ocean carbon flux as well as to assess mitigations or make societal decisions, to which we now
511 turn.

512

513

514 **Figure 5-** Sources of uncertainty averaged over the 20 year mean periods. The rows represent different sources as
 515 explained in the methods section at each grid cell. Columns represent different times: the recent (1995-2015), mid-
 516 century (2040-2060), and late-century (2080-2100) anomalies relative to the 1995-2015 mean. The numbers are
 517 correlation coefficients of each map with the 1995-2015 mean anomaly relative to the 1850-1900 mean (Fig. 1c).

518

519 3.4 Detectability

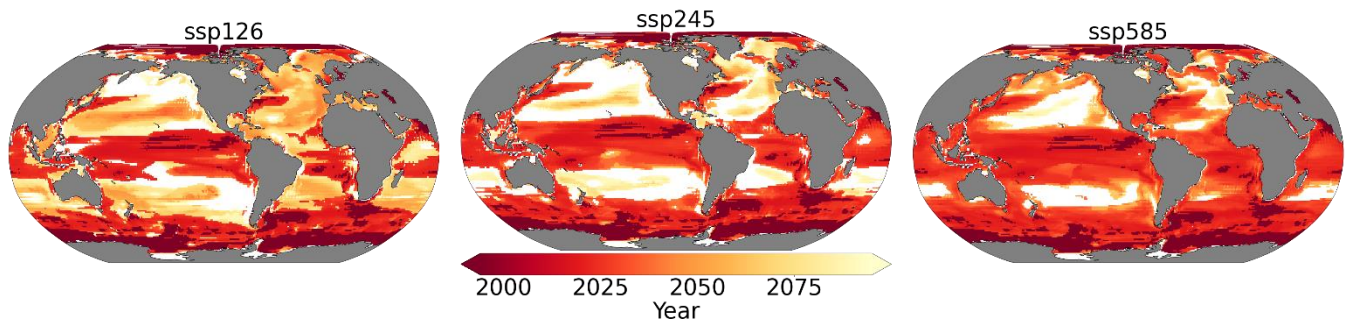

520 Detectability refers to the ability to robustly identify a forced signal, above and beyond the noise induced by internal
 521 climate variability. Previous studies have largely presented a single time of emergence (Lovenduski et al. 2016,
 522 Schlunegger et al., 2019, McKinley et al., 2016). However, understanding the regional differences, timescales, and
 523 scenario dependence in the detectability of human induced trends in the ocean surface carbon flux is important for
 524 informing observational strategies that aim to measure these changes.

525

526 We measure the detectability of the CMIP6 multi-model ensemble mean ocean surface carbon flux anomaly using
527 the time of emergence at each grid point. We use this finest scale as it is the most applicable to observational
528 communities for sampling. The time of emergence is defined as the point at which the forced signal, given by the
529 multi-model ensemble mean flux anomaly, relative to 1995-2015, emerges from internal variability, given by the
530 CanESM5 SMILE.

531
532 The signal in human induced surface ocean carbon flux emerges beyond the internal variability earlier in the highly
533 active regions than anywhere else. This is evident in the Equatorial Pacific, Southern Ocean, the western boundary
534 currents of the gyre systems, and their extensions (Fig. 6). Ocean regions such as the centres of the mid-latitude
535 gyre systems and the NE Pacific show late emergence times and, in some cases, no detectability of the signal in
536 any of the scenarios by 2100. Convergent large-scale circulation and strong stratification in these regions isolates
537 the surface from the deep ocean reducing their capacity to hold large amounts of carbon (McKinley et al., 2016).
538 An absence of mechanisms constantly drawing surface ocean CO₂ out of equilibrium with atmospheric CO₂ lets
539 the surface water equilibrate with and adjust to the atmosphere on short time scales. Significant changes thus do
540 not take place in the sink as the atmospheric CO₂ levels change and scenario uncertainty is lowest in the same
541 regions (see Fig. 4). This is consistent with the results from Sect. 3.3, in which we showed that internal variability
542 is a significant source throughout the century in the NE Pacific, with scenarios never emerging out of the range of
543 internal variability (Fig. 4a, b). Our results for the broad patterns in the multi-model mean TOE are largely
544 consistent with previous studies, suggesting they are robust and insensitive to for the method of estimating internal
545 variability. These include studies from CMIP5 models such as McKinley et al., (2016) that assumed time/scenario
546 independent internal variability, and Schlunegger et al., (2020) that used only high emission scenario internal
547 variability from four large ensembles to show there is strong agreement between LEs TOE both locally and
548 spatially. Our results argue for focusing observational efforts on the highly active regions in order to detect human
549 influence on the ocean carbon sink. Meanwhile, they imply that observational timeseries in quiescent regions, such
550 as Ocean Station Papa in the NE Pacific, need to interpret any observed trends with care, since internal variability
551 tends to dominate over human induced trends.

552
553
554

555

556 **Figure 6-** Time of emergence of the multi-model mean anomaly under different scenarios. White regions indicate
 557 where the anthropogenic signal cannot be detected even towards the end of the century.

558

559 Time of emergence strongly depends on the future scenario. Schlunegger et al. (2020) show for two scenarios that
 560 modest (~10 yr) TOE differences between different ESMs under strong anthropogenic forcing can evolve into
 561 pronounced (60+ yr) TOE differences with moderate mitigation. Here, we make use of three scenarios including a
 562 strong-mitigation scenario and account for scenario dependence of internal variability in our approximation using
 563 CanESM5. On average, scenarios with smaller forced trends emerge later as the size of the forced trend is critical
 564 to the time of emergence (Fig. 2-a). The TOE is earliest on average over the global ocean in ssp585, while it is later
 565 in ssp245, and later still in ssp126, consistent with the imposed changes in atmospheric CO₂ concentration. The
 566 exceptions are quiescent regions that show earlier detectability for ssp126 compared to other scenarios; these
 567 exceptions are associated with larger (but negative) anomalies in the latter half of the century under ssp126 which
 568 has negative emissions (compare panels d-f, and g-i on Fig. 1). Internal variability does evolve somewhat
 569 differently for each scenario, but this is secondary (Fig. S2). Schlunegger et al. (2020) argues that variables such
 570 as air-sea CO₂ flux which are sufficiently sensitive to emissions emerge early, prior to significant divergence among
 571 future scenarios. Consistent with this result, our results indicate that there is broad agreement between scenarios in
 572 the TOE patterns, when considering the highly active regions. Interestingly, our scenario-specific TOE shows that
 573 differences between scenario TOEs is associated with how sensitive different regions are to emission scenarios.
 574 More specifically, comparison to the maps of scenario uncertainty (Fig. 5) shows that TOE differs more across
 575 scenarios in regions where scenario uncertainty is small, such as the aforementioned subtropics Ekman convergence
 576 regions. Elsewhere, the emergence happens before scenarios diverge significantly. Our results suggest that under
 577 the rapidly rising atmospheric CO₂ concentrations seen in ssp585, the human signal in the ocean carbon sink will
 578 be detectable across much of the global ocean over the coming few decades. However, under strong mitigation
 579 scenarios, such as ssp126, early emergence (earlier than 2030) will only occur in isolated regions while counter-
 580 intuitively, less percentage of the global ocean remains non-emergent by 2100.

581 4. Conclusions

582 Ocean uptake of the increasing atmospheric CO₂ in the 21st century is concentrated in a few active regions with 70
583 percent of the total sink occurring in less than 40 percent of the global ocean. We analyze the results from the
584 CMIP6 multi-model mean for the current state of the ocean (1995-2015), and the middle (2040-2060) and late
585 (2080-2100) 21st century relative to the current state for three scenarios. We show that future changes in the sink
586 are projected to mostly take place within the same historical highly active regions. This result implies that known
587 regions of high historical uptake, including the North Atlantic and Southern Ocean, are the same regions to
588 prioritize for observing the future evolution of the sink. Our results extend the argument of Wang et al. (2016) that
589 the historical state is a good predictor of the future state to spatial patterns of change.

590

591 We show that the CMIP6 multi-model mean provides a consistent estimate of the spatial patterns of the sink, and
592 the trend in the sink (globally), compared to the observation-based data product dataset of Landschützer et al.
593 (2016). These results suggest the CMIP6 models are valid tools for understanding the past and future evolution of
594 the ocean carbon sink, particularly at broad spatial scales. A notable area of disagreement is that the Landschützer
595 et al. (2016) data shows larger decadal variability at the global scale than seen in any CMIP6 model and the range
596 of internal variability from CanESM5 large ensemble. Gloege et al. (2021) shows that the SOM-FFN method
597 overestimates the magnitude of decadal variability on the global scale due to the amount of gap filling.

598

599 We have shown that the magnitude of uncertainty and its partitioning among different sources differs with scale
600 and location. On the global scale, scenario uncertainty is the largest source of uncertainty followed by model
601 uncertainty and internal variability for CMIP6 models. These results are in agreement with previous studies from
602 CMIP5 models (Lovenduski et al., 2016; Schlunegger et al., 2020). As the scales of integration (averaging) get
603 finer, model and internal variability become the dominant sources, respectively. Testing the results on two ocean
604 regions of about the same size, one in the NE Pacific and one in the NW Atlantic shows that - while consistent with
605 the results of the scale dependence analysis - the relative importance of the sources of uncertainty also differs with
606 location. Our test here extends the analysis Schlunegger et al. (2020) with a focus on the association of the location
607 dependence with whether the regions have highly active carbon sinks. Notably, in highly active regions, such as
608 the NW Atlantic, scenario uncertainty is large, whereas in more quiescent regions, such as the NE Pacific, internal
609 variability is more significant. The dependence of internal variability on the scenario with time is another interesting
610 finding that could be the subject of future studies for a better understanding of the driving mechanism and the
611 degree of dependence on the future emissions and/or concentrations.

612

613 The patterns of high future CO₂ uptake uncertainty are highly correlated with the patterns of historical uptake. The
614 correlation coefficients are highest for scenario uncertainty, indicating that the highly active regions have the
615 potential for the sink to evolve according to the atmospheric CO₂ concentration, while the rest of the ocean basins
616 do not respond strongly to changes in atmospheric CO₂ represented by the different scenarios. This finding has
617 implications for assessment of the mitigations and effects of socioeconomic decisions. Our results here are
618 significant in that they show that regions of future uncertainty are largely associated with known regions of
619 significant historical uptake.

620

621 Patterns seen in the time-of-emergence have implications for planning observational campaigns for detection of a
622 signal (Schlunegger et al. 2019 & 2020). Furthermore, there is reverse association between how sensitive a region
623 is to scenario differences (apparent in the scenario uncertainty patterns) and how sensitive the TOE is to scenarios.
624 Our results show that caution should be taken in interpreting the observed changes in regions such as NE Pacific
625 associated with late time of emergence of the signal from the decadal (internal) variations. On the other hand,
626 regions such as the Equatorial Pacific, the Gulf Stream and Kuroshio and their extensions, and the Southern Ocean,
627 should be the focus of consistent and expanded sampling for detection of the forced signal. Additionally, the
628 patterns in sources of uncertainty show that model uncertainty is largest in the Southern Ocean, consistent with
629 Frölicher et al., 2015. The sink in the Southern Ocean is driven by complex mechanisms involving coupled ocean-
630 atmosphere-ice interactions that require better representation in ocean biogeochemical models. Significant progress
631 in reducing uncertainties can be expected from new methods of bringing together models and observations
632 (Frolicher et al. 2016). Our results provide a motivation to focus modelling as well as observational efforts on the
633 known highly active regions of historical uptake.

634

635 Finally, we have shown that internal variability shows clear changes in time and depends on the scenario. The
636 emergence of Large Ensembles (LEs) allows for quantification of these variations if enough ensemble members
637 are available to fully capture internal variability using realizations that start from different initial conditions. Our
638 use of the CanESM5 LE allows for us to account for the nonstationary of internal variability in time, like in
639 Schlunegger et al. (2020) but with the advantage of also accounting for scenario dependence. Model
640 intercomparison indicates that ESMs show differences in natural variability (Schlunegger et al. 2020). Nonetheless,
641 our analysis of the global scale, of scale dependence, and of the patterns seen in Time of Emergence are consistent
642 with previous studies, despite the potential sensitivity to the use of CanESM5 LE. Our methodology to correct for
643 internal variability from model spread, without filtering or having a large ensemble for each ESM (which would

644 limit the number of ESMs that can be included and, consequently, underestimate model uncertainty) lays the
645 foundation for future studies when LEs are available from more ESMs and advocates for more modelling groups
646 to provide such LEs in order to achieve an even more robust estimate of internal variability as the mean across
647 different ESMs.

648

649 **Data Availability**

650 The data used in this study is part of the World Climate Research Programme's (WCRP) 6th Coupled Model
651 Intercomparison Project (CMIP6) open access data. For details on accessibility see section S1 in the Supplements.
652 The SOM-FFN data (Landschützer et al., 2017) from Landschützer (2016) can be accessed through the [National
653 Oceanographic Data Center](https://www.nodc.noaa.gov/archive/arc0105/0160558/3.3/data/0-data/) (NODC, <https://www.nodc.noaa.gov/archive/arc0105/0160558/3.3/data/0-data/>)
654 operated by the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

655 **Author Contribution**

656 Parsa Gooya conducted the formal analysis, visualization, and original draft preparation. Conceptualization, and
657 methodology development and validation were a collaboration of the three authors, mainly developed by Parsa
658 Gooya with contributions from Neil Swart in development, validation, and revision and Roberta Hamme in
659 validation and revision. Neil Swart and Roberta Hamme provided supervision and reviewing and editing of the
660 manuscript and methodology. Funding acquisition was carried out by Roberta Hamme.

661 **Competing of interest**

662 The authors declare that they have no conflict of interest.

663 **Acknowledgments**

664 This work was supported by the Marine Carbon Sink project, funded by the Natural Sciences and Engineering
665 Research Council of Canada through the Advancing Climate Change Science in Canada program. We thank Jim
666 Christian for helpful suggestions on a draft of the manuscript.
