8 **Abstract.** As a major sink for anthropogenic carbon, the oceans slow the increase of carbon dioxide in the  
9 atmosphere and regulate climate change. Future changes in the ocean carbon sink, and its uncertainty at a global  
10 and regional scale, are key to understanding the future evolution of the climate. Here, we conduct a multimodel  
11 analysis of the changes and uncertainties in the historical and future ocean carbon sink using output data from the  
12 latest phase of the Coupled Model Intercomparison Project: CMIP6, and observations. We show that the ocean  
13 carbon sink is concentrated in highly active regions - 70 percent of the total sink occurs in less than 40 percent of  
14 the global ocean. High pattern correlations between the historical and projected future carbon sink indicate that  
15 future uptake will largely continue to occur in historically important regions. We conduct a detailed breakdown of  
16 the sources of uncertainty in the future carbon sink by region. Scenario uncertainty dominates at the global scale,  
17 followed by model uncertainty, and then internal variability. We demonstrate how the importance of internal  
18 variability increases moving to smaller spatial scales and go on to show how the breakdown between scenario,  
19 model, and internal variability changes between different ocean basins, governed by different processes. Moreover,  
20 we show that internal variability changes with time based on the scenario. As with the mean sink, we show that  
21 uncertainty in the future ocean carbon sink is also concentrated in the known regions of historical uptake. The  
22 resulting patterns in the signal-to-noise ratio have strong implications for observational detectability and time of  
23 emergence, which varies both in space and with scenario. Our results suggest that to detect human influence on the  
24 ocean carbon sink as early as possible, and to efficiently reduce uncertainty in future carbon uptake, modelling and  
25 observational efforts should be focused in the known regions of high historical uptake, including the Northwest  
26 Atlantic and the Southern Ocean.

## 27 1. Introduction

28 Recent increases in greenhouse gases have trapped additional heat relative to the pre-industrial era and raised  
29 Earth's average temperature. Carbon dioxide (CO<sub>2</sub>) is the primary driver of the global warming in the industrial  
30 period (Masson-Delmotte et al., 2021). The concentration of atmospheric CO<sub>2</sub> has increased from approximately  
31 277 parts per million (ppm) in 1750 (Joos et al., 2008), the beginning of the Industrial Era, to 409 ppm in 2019.  
32 However, less than half of the anthropogenic CO<sub>2</sub> has remained in the atmosphere; the remaining CO<sub>2</sub> has been  
33 taken up by the natural carbon sinks of the ocean and the terrestrial biosphere. Specifically, the global ocean  
34 absorbed ~26% of the total CO<sub>2</sub> emissions during 2011-2020 (Friedlingstein et al., 2021).

35  
36 The ocean's capacity to absorb increasing amounts of anthropogenic CO<sub>2</sub> is not uniformly distributed (McKinley  
37 et al., 2016). Despite increasing atmospheric CO<sub>2</sub> concentrations, the air-sea CO<sub>2</sub> flux does not change much in the  
38 subtropical gyres. The regions where ocean carbon uptake notably increases are those with strong exchange  
39 between the surface and the deep ocean (McKinley et al., 2016). Even within regions there are large variations in  
40 the sink. The Northeast Pacific, for instance, is a net sink for atmospheric CO<sub>2</sub>. However, the region includes  
41 diverse oceanographic areas such as open ocean, continental margins, and fjords, leading to large spatial variability  
42 in the direction of the CO<sub>2</sub> sea-air flux (Sutton et al., 2017; Takahashi et al., 2006). In the Southern Ocean, the  
43 spatial superposition of natural and anthropogenic CO<sub>2</sub> fluxes leads to a relatively strong uptake band between  
44 approximately 55°S and 35°S (Gruber et al., 2019). However, south of the Polar Front (55°S), the different  
45 estimates agree less well (Gruber et al., 2019). Supported by measurements based on biogeochemical floats (Gray  
46 et al., 2018; Williams et al., 2018), Gruber et al. (2019) argues that the region was most likely a small source in  
47 2019.

48  
49 Earth System Models (ESMs) are the primary tool for projecting the future evolution of ocean carbon uptake on  
50 subannual to centennial timescales. However, quantitative projections from ESMs across these timescales are  
51 subject to considerable uncertainty, particularly at regional and local scales (Friedrich et al., 2012; Frölicher et  
52 al., 2014; Hauck et al., 2015; Laufkötter et al., 2015; Roy et al., 2011; Tjiputra et al., 2014) where less averaging  
53 is done and more diverse mechanisms dominate. Projection uncertainty varies with lead time, spatial averaging  
54 scale, and from region to region. For example, Lovenduski et al. (2016) showed a spatially heterogeneous pattern  
55 of projection uncertainty in CO<sub>2</sub> flux projections over 17 regions; at the scale of the California Current System,  
56 uncertainty was relatively higher compared to the global scale. If ESMs are to be used to quantify future changes

57 in ocean carbon uptake, especially across shorter timescales and at regional spatial scales, and to inform  
58 observational campaign planning, their uncertainties must be well known and well understood (Lovenduski et al.,  
59 2016).

60

61 A systematic characterization of projection uncertainty has become possible with the advent of the Coupled Model  
62 Intercomparison Project (CMIP), as a number of climate models of similar complexity provided simulations over  
63 a consistent time period and with the same set of emissions scenarios (Lehner et al., 2020). We consider three main  
64 types of projection uncertainty, as described by Hawkins and Sutton (2009) (hereafter HS09):

65

66 **Uncertainty due to internal variability:** Internal variability is the unforced natural climate variability resulting  
67 from the internal processes in the climate system. Modes such as the El Niño–Southern Oscillation, North Atlantic  
68 Oscillation, Atlantic Multidecadal Oscillation, Pacific Decadal Oscillation, and Southern Annular Mode (SAM)  
69 contribute, along with others, to this internal variability. The real world follows only one of an infinite possible  
70 number of *realizations* of internal variability, and the future evolution of internal variability is not predictable  
71 beyond short timescales. Climate model simulations do not attempt to reproduce the exact observed evolution of  
72 internal variability, but produce their own, unique realizations that aim to capture the correct statistics of this  
73 variability. Hence, our analysis must account for internal variability, both when comparing historical model  
74 simulations to observations, and when considering uncertainties in the future ocean carbon sink. In HS09, a fourth-  
75 order polynomial fit to simulated global and regional temperature timeseries represented the forced response, while  
76 the residual from this fit represented the internal variability. However, this approach could possibly conflate internal  
77 variability with the forced response in cases where low-frequency (decadal-to-multidecadal) internal variability  
78 exists, or when the forced signal is weak, which makes the statistical fit a poor estimate of the forced response  
79 (Kumar and Ganguly, 2018). In this study, we instead use a Single-Model Initial-condition Large  
80 Ensemble (SMILE) to robustly quantify the simulated forced response and internal variability using ensemble  
81 statistics (Lehner et al., 2020). A SMILE is an ensemble of model realizations that each starts from different initial  
82 conditions but uses the same model and forcing, and provides representations of the climate system that are  
83 equivalent except for internal variability.

84 **Uncertainty due to model structure:** Each model has a specific way of representing the physical world. Models  
85 differ in their resolution, structure, numerics, and parameterization of processes. These differences cause models  
86 to respond differently to the same forcing. For example, the CMIP5 model simulations run under Representative

87 Concentration Pathway 8.5 (RCP8.5) project a wide range of cumulative anthropogenic carbon storage by 2100  
88 (320–635 Pg-C) (Ciais and Sabine, 2013) due to both internal variability and model uncertainty (Lovenduski et al.,  
89 2016).

90 **Uncertainty due to emission scenario:** The future of the climate system depends on human activity and our  
91 emission of climate active gases that change radiative forcing. Future emissions are highly uncertain, given our  
92 inability to project the complex changes in society and technology upon which they depend. As a result, future  
93 simulations are run with a range of possible “scenarios” for how future emissions (or atmospheric concentrations)  
94 will evolve under different socioeconomic storylines. These scenarios are prescribed via the internationally  
95 coordinated experiments organized by the Coupled Model Intercomparison Project. Since the future emission  
96 trajectory is unknown, these future simulations are referred to as projections, rather than predictions. Projections  
97 of future ocean carbon uptake from ESMs are greatly influenced by the choice of emission scenario (Lovenduski  
98 et al., 2016). For example, the cumulative oceanic storage of anthropogenic carbon in CMIP5 models by 2100  
99 ranges from 110–220 Pg-C under RCP2.6 to 320–635 Pg-C under RCP8.5 (Ciais and Sabine, 2013).

00 In this paper we start by analysing the regional patterns of historical ocean carbon uptake and how they are projected  
01 to change in the future (Sect. 3.1). Then, we examine the partitioning among different sources of uncertainty (Sect.  
02 3.2) and the scale dependence of this partitioning analysis (Sect. 3.3) to understand how the uncertainty and  
03 distribution among sources differ based on scale of integration and region of interest (Sect. 3.4). The final section  
04 explores the detectability of the model projected signal given the uncertainty imposed by internal variability, in  
05 order to make useful suggestions for future observations.

## 06 **2. Data and Methods**

### 07 2.1 Model Data Selection

08 Here we use results from models selected from the 6<sup>th</sup> Coupled Model Intercomparison Project (CMIP6; Eyring et  
09 al., 2016). Models are chosen based on availability, meaning all models that provided at least one realisation for  
10 air-sea CO<sub>2</sub> flux (fgco2) for the experiments of interest. One realization of each model over the historical period  
11 and three scenarios that represent the low (ssp126), mid (ssp245), and high (ssp585) ranges of future atmospheric  
12 CO<sub>2</sub> concentrations are analysed. A total of 16 models met these criteria, out of which 3 were excluded as outliers  
13 (see section S1 in the Supplements). To maintain equal sampling, only one realization of each model is selected,

14 except when specifically using the large ensembles to assess internal variability. Finally, since the ocean component  
15 of the models may be on different grids, all model data are remapped to a regular one-by-one-degree grid.

16

## 17 2.2 Sources of uncertainty

18 Three sources of uncertainty are considered following the approach of HS09. Total uncertainty is composed of  
19 internal, model, and scenario uncertainty in equation 1, which assumes that each of these sources is independent.  
20 Here, each source of uncertainty is considered as a function of time ( $t$ ) and location ( $l$ ) (Lovenduski et al., 2016):

21

$$22 \quad U_T^2(t, l) = U_I^2(t, l) + U_M^2(t, l) + U_S^2(t, l) \quad (1)$$

23

24 where  $U_T(t, l)$  is total uncertainty,  $U_I(t, l)$  is internal variability,  $U_M(t, l)$  is model uncertainty, and  $U_S(t, l)$  is  
25 scenario uncertainty. The fractional uncertainties for each source are calculated as  $\frac{U_I^2}{U_T^2}$ ,  $\frac{U_M^2}{U_T^2}$ , and  $\frac{U_S^2}{U_T^2}$  (Lovenduski et  
26 al., 2016).

27

28 HS09 assume  $U_I(t, l)$  to be constant in time and use a 4<sup>th</sup> degree polynomial fit to measure internal variability as  
29 the spread over time and scenario of the residuals for each models signal relative to the fitted signal. We show in  
30 the Supplements (see section S2) that internal variability depends on time and scenario, so a better estimate of  
31 internal variability should account for these variations. Here, we quantify internal variability as two times the  
32 standard deviation of the annual carbon sink across many realizations from a Single Model Initial Condition Large-  
33 ensemble based on CanESM5:

34

35

$$36 \quad U_I(t, l) = 2 \sqrt{\frac{1}{N_S} \sum_{s=1}^{N_S} \text{Var}(\text{CanESM5 Large Ensemble})} \quad (2)$$

37

38 where  $s$  indicates each scenario ( $N_S$  is the number of scenarios) and Var indicates the variance over the large  
39 ensemble of CanESM5. In the CanESM5 SMILE, each realization starts from different initial conditions which  
40 are drawn from points separated by 50 years in the piControl simulation. Thus, the spread across the realizations

41 gives a robust estimate of the internal variability, including sampling over longer term ocean variability. Internal  
42 variability is an important component of the uncertainty that is not reducible and results from the chaotic nature of  
43 the climate system. Further details regarding the estimation of internal variability are explained in the Supplements  
44 (see section S2). CanESM5 is the only model that has a large enough ensemble over the entire timeline and set of  
45 experiments to make this estimate.

46

47

48 Model uncertainty is calculated by taking the variance across the forced signal of all available models for each  
49 scenario, averaging over the three scenarios, and then reporting twice the square root of the result (Eq. 3).

$$50 \quad U_M(t, l) = 2 \sqrt{\frac{1}{N_S} \sum_{s=1}^{N_S} \text{Var}_m(F(m, s, t, l))} \quad (3)$$

51 where  $\text{Var}_m$  means the variance taken across different models for individual times and scenarios,  $m$  indicates each  
52 model, and  $t$  stands for time.  $F(m, s, t, l)$  is the forced signal and can be related to each realization as follows:

53

$$54 \quad T(m, s, t, l) = F(m, s, t, l) + R(m, s, t, l) \quad (4)$$

55

56 Where,  $T(m, s, t, l)$  represents the reported output, i.e. each realization, but must be corrected for internal  
57 variability.  $R(m, s, t, l)$  is the residual from the forced signal caused by internal variability. Here, the variance in  
58 the forced signal across all models is calculated by correcting the total variance across each model realization for  
59 the variance caused by internal variability. The corrections are done by subtracting the variance across the same  
60 number of CanESM5 ensemble members as the multi-model ensemble (13 members) from the spread across one  
61 realization of each of the 13 models. For this correction only, the sample sizes (13) are kept the same so that the  
62 internal variability removed from the variance across the models' first realizations is not overestimated by a well  
63 sampled 50-member ensemble (see section S3 in the Supplements).

64

65  $U_s(t, l)$  is the scenario uncertainty. Scenario uncertainty is measured as twice the standard deviation (square root  
66 of variance) across scenarios of the multi-model mean signal (Eq. 5).

67

68

$$U_S(t, l) = 2 \sqrt{\text{Var}_m \left( \frac{1}{N_m} \sum_{m=1}^{N_m} T(m, s, t, l) \right)} \quad (5)$$

69

where  $N_m$  is the number of models. The multi-model mean across the first realizations of the 13 models gives the multi-model forced response and does not require correction for internal variability as done for model uncertainty before.

72

73

We conduct analysis on three different scales: single grid point (one-degree resolution), regional, and global. When regional and global analysis is done, the dependence on location is taken away by integrating and averaging over that region or the whole global ocean.

76

77

### 2.3 Time of Emergence

78

In order to know when the forced response is distinguishable from internal variability, time of emergence is calculated following the approach of McKinley et al. (2016). The time of emergence is the first year when the multi-model mean anomaly is larger than internal variability – two times the standard deviation across the 50 member CanESM5 ensemble - for five consecutive years (the first year of this five-year period is reported as the time of emergence). The result is reported at each grid point for the 10-year running mean smoothed anomaly relative to the 1995-2015 mean (detection of a change relative to the current state of the ocean).

84

85

86

### 2.4 Scale Dependence

87

Finally, the scale dependence of the sources of uncertainty is measured at year 2050 using ssp245 for internal variability and model uncertainty, and using all scenarios for scenario uncertainty. The analysis is done by moving a sliding sample window of a given area across the earth, and then repeating with a larger and larger window until all scales from  $<100 \text{ km}^2$  to the whole Earth are considered. The average for all rectangles of the same ocean area across the global ocean for each source of uncertainty is reported.

92

93 **3. Results and Discussion**

94 3.1 Global Analysis

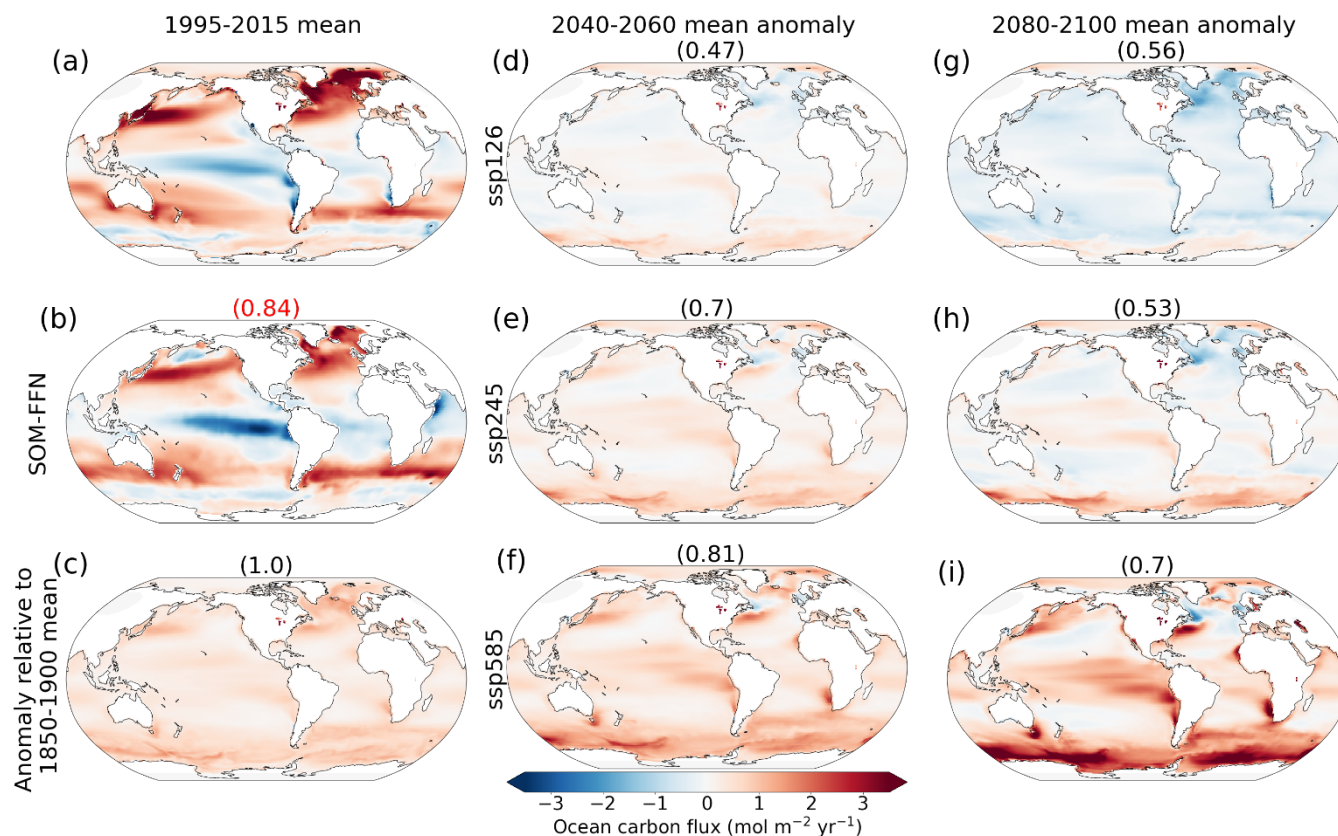

95 The pattern of the carbon sink in the CMIP6 multi-model ensemble mean from the historical experiment over 1995-  
96 2015 matches that of the Landschützer (2016) Self Organizing Map - Feed Forward Neural Network (SOM-FFN)  
97 observation-based data product estimate (correlation coefficient of 0.84, compare Figs. 1a and 1b). We use the  
98 multi-model mean response to external forcing as a more robust estimate of the forced climate signal than the  
99 response of any single model (Tebaldi & Knutti, 2007). When compared to the observation-based data product, the  
:00 CMIP6 multi-model mean shows a larger sink (positive flux) in the North Atlantic and North and North-West  
:01 Pacific but a smaller sink in the Southern Ocean (Fig 1a, b). Additionally, the observation-based data product shows  
:02 a larger source in the Equatorial Pacific and Indian Ocean than the CMIP6 multi-model ensemble.

:03  
:04 While most of the global ocean shows a net sink relative to the pre-industrial era, the largest change takes place in  
:05 regions such as the North Atlantic, Southern Ocean, Equatorial Pacific, and western boundary currents of the mid-  
:06 latitude gyre systems in the Pacific and Atlantic Oceans (Fig. 1c). These regions of largest changes in the carbon  
:07 sink seem to be the regions where there is a surface-depth connectivity. We refer to these regions as “hotspots”  
:08 from here on. These results for CMIP6 are consistent with those for CMIP5 shown by McKinley et al. (2016).

:09  
:10 The regions of largest future carbon uptake, relative to the 1995-2015 mean, are the same regions responsible for  
:11 most of the uptake over the historical period. The correlation coefficients on top of each panel in Fig. 1 (except 1b)  
:12 represent the correlation between future absolute anomalies, relative to 1995-2015, and anomalies in 1995-2015,  
:13 relative to the pre-industrial era. The high correlations indicate that regions that have been most active in carbon  
:14 sequestration since the pre-industrial era are the same regions that will continue to change most into the future,  
:15 particularly with larger increases in atmospheric CO<sub>2</sub> (ssp585).

:16  
:17  
:18

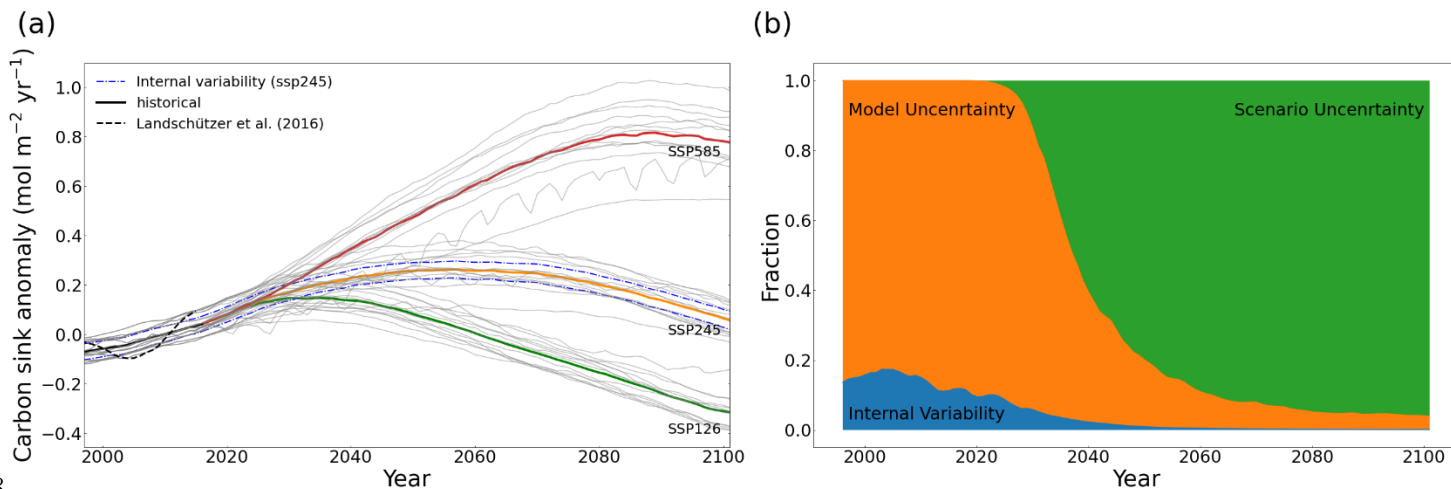

19  
 20 **Figure 1-** CMIP6 multi-model mean maps using one realization of each model. Columns represent different time periods,  
 21 being the recent time (1995-2015 mean), mid-century (2040-2060 mean), and late-century (2080-2100 mean). Note: the sink  
 22 is positive into the ocean. The first column shows (a) the carbon sink over 1995-2015, (b) Landschützer et al. (2016) SOM-  
 23 FFN product, and (c) the anomaly relative to the 1850-1900 mean. Other panels are anomalies relative to the 1995-2015  
 24 multi-model mean (panel a). Panels d through i show different scenarios. Numbers above each map are correlation  
 25 coefficients between the absolute value of the change relative to 1995-2015 with the 1995-2015 anomaly map relative to the  
 26 pre-industrial era in panel c, except the red number at the top of panel b that is the correlation coefficient with this panel and  
 27 panel a.

28  
 29 The multi-model mean sink anomalies for two future periods, 2040-2060 and 2080-2100, show how the sink is  
 30 projected to evolve, relative to 1995-2015, according to time and choice of emission scenario (Fig. 1d-i). The  
 31 regional patterns show mostly positive anomalies at mid-century. Towards the end of the century, however,  
 32 negative anomalies are expected in ssp126, as emissions turn negative in the late-century in this scenario. The late-  
 33 century anomalies are predominantly positive in ssp585 which corresponds to the highest emission scenario, while

34 ssp245 is somewhere in between, with regions of positive and negative anomalies. The globally integrated ocean  
35 carbon uptake rates are summarized in Table 1.

36  
37

38  
39 **Figure 2-** (a) Thick lines are multi-model means of the global mean ocean carbon sink anomaly timeseries relative to 1995-  
40 2015. Individual models averaged for the means are plotted as thin grey lines in the background. The black dashed line  
41 shows the Landschützer et al. (2016) SOM-FFN product. The blue dashed lines show internal variability for ssp245. (b)  
42 Timeseries showing the breakdown of uncertainty to different sources with time for the global ocean carbon sink anomaly.  
43 The internal and model uncertainty are averaged for different scenarios.

.57

.58 **Table 1-** CMIP6 multi-model mean globally averaged carbon sink anomalies (with ranges within the 20-yr period in  
 .59 parentheses) relative to the 1995-2015 mean (in mol-C m<sup>-2</sup> yr<sup>-1</sup>) and Internal variability (with model uncertainty in  
 .60 parentheses) for the globally averaged ocean carbon sink anomalies for the three scenarios and the average values across  
 .61 scenarios.

.62

.63

.64 The trends in ocean carbon sink anomalies over 1995-2015 are statistically consistent between the CMIP6 multi-  
 .65 model ensemble mean and the Landschützer et al. (2016) observation-based data product (Fig. 2-a), based on the  
 .66 test from Santer et al. (2008). However, the SOM-FFN based time-series shows a larger multi-decadal variability  
 .67 than seen in individual model realizations, and is larger than the range of internal variability estimated from the  
 .68 CanESM5 SMILE. The difference could be due to either overestimation of internal variability by the SOM-FFN  
 .69 method, or underestimation of the internal variability in the models. Given that on regional scales the SOM-FFN  
 .70 data is within the range of internal variability projected by the CMIP6 large-ensemble of CanESM5 (see Sect. 3.3),  
 .71 and that there are significant gaps in the spatial and temporal sampling that underlies the Landschützer et al. (2016)  
 .72 estimate, it seems plausible that the discrepancy is largely due to overestimation of internal variability on the global

.73 scale by the SOM-FFN technique. This is consistent with the findings of Gloege et al. (2021), which showed that,  
.74 globally, the magnitude of decadal variability is overestimated by 21% by the SOM-FFN technique, attributed to  
.75 the amount of data filling.

.76

.77 On the global scale, model uncertainty is the dominant source of uncertainty in the historical period, but scenario  
.78 uncertainty comes to dominate later (Fig. 2b). Over the 1995-2020 period, model uncertainty explains around 85%  
.79 of the total uncertainty. Scenario uncertainty becomes the dominant source after 2040, explaining almost 40% of  
.80 the total uncertainty at that time and more than 90% by the end of the century. Internal variability explains 15% at  
.81 the start of the century but only around 1% by the end. It is worth mentioning that the decreased shares associated  
.82 with model and internal variability do not mean that model or internal variability decrease in an absolute sense;  
.83 rather, their importance relative to scenario uncertainty declines. Internal and model uncertainty of the global  
.84 carbon sink change with time, based on the scenario (Table 2); high emission scenarios such as ssp585 show a  
.85 larger change for both internal and model uncertainty. When averaged for the three scenarios, a constant absolute  
.86 increase in both model and internal variability is seen through the century until 2080-2100 when the values either  
.87 do not change or decrease slightly (Table 1).

.88

.89

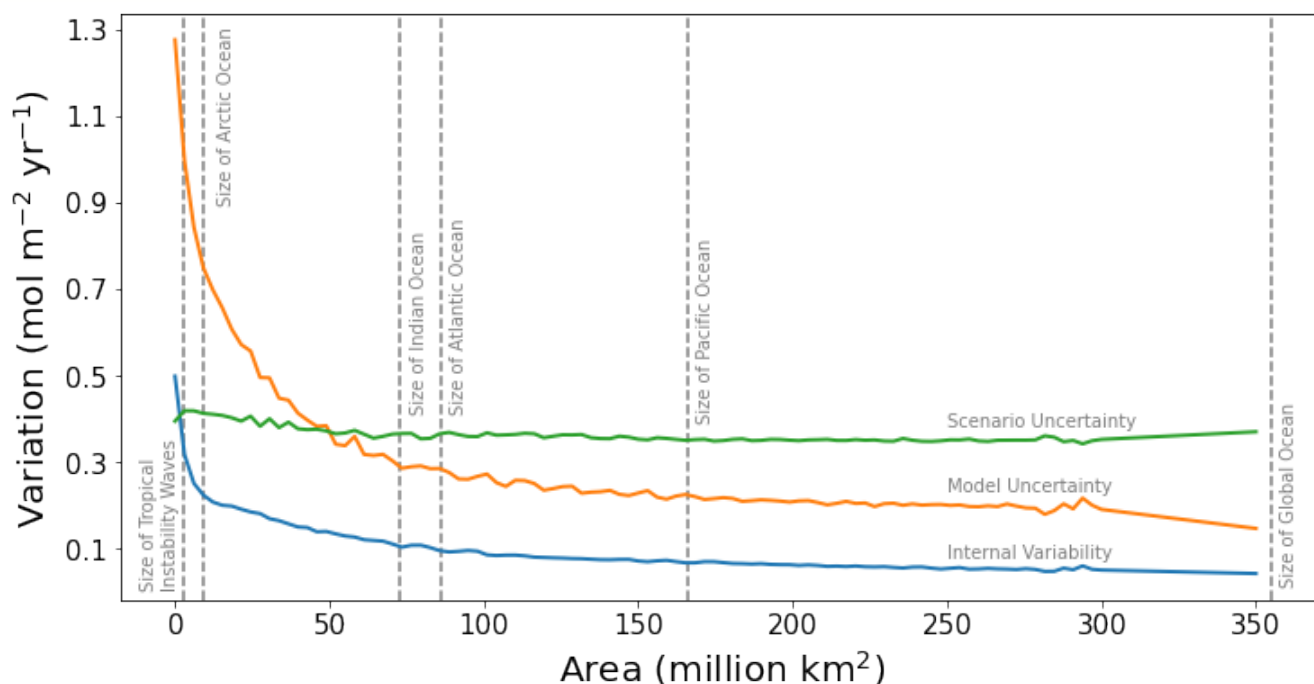

### .90 3.2 Dependence of the sources of uncertainty on spatial scale

.91 It is generally accepted that uncertainty and, most importantly, internal variability grow larger as the averaging  
.92 (integration) scale gets finer, because on larger scales the variability is averaged out. Lovenduski et al. (2016)  
.93 showed this scale dependence by comparing an area covering the California Current System with the global ocean.  
.94 Here, we provide a continuous view of change in variability across scales from the global to grid scale, by  
.95 measuring how variability changes relative to scale on average (Fig. 3). At the global scale, the dominant source  
.96 of uncertainty is scenario uncertainty, followed by model and internal variability respectively, consistent with Fig.  
.97 2b. However, as the averaging (integration) scale gets finer, model and internal variability grow rapidly, while  
.98 scenario uncertainty only grows slightly on average (over all regions of this size). At an averaging (integration)  
.99 scale with an area finer than 75 million km<sup>2</sup> (on average around the globe), model uncertainty becomes the dominant  
.00 source of uncertainty, and at a scale finer than 3 million km<sup>2</sup>, internal variability becomes larger than scenario  
.01 uncertainty. However, while this holds true on average over the globe, scale dependence can vary in its nature  
.02 depending on the particular region being sampled.

.03

04

05

06 **Figure 3-** Sources of uncertainty versus area of averaging. Internal variability is based on ssp245 year 2050 of all CanESM5  
07 members. Scenario uncertainty is based on all scenarios of the 13 models at year 2050 and model uncertainty is the corrected  
08 standard deviation of our 13 models at year 2050 of ssp245. The values of uncertainties are averaged over all different  
09 rectangular areas of each size that can scan the globe. Dashed lines indicate the size of the averaging window and not a  
10 specific location.

11

### 12 3.3 Regional Analysis

13 The findings of the globally averaged scale dependence analysis were tested by repeating the uncertainty  
14 breakdown for two specific regions: one between 20°- 60° N in the North East Pacific (NE Pacific) between 130°-  
15 160° W and one in the North West Atlantic (NW Atlantic) between 40°- 70° W at the same latitude. The NW  
16 Atlantic region represents a hotspot while the NE Pacific region is more typical of quiescent ocean regions. By  
17 quiescent ocean regions we refer to regions where strong stratification limits the vertical transport of carbon by  
18 isolating the surface.

19

20 The variation across scenarios is at all times smaller than internal variability in the NE Pacific (Fig. 4a). This  
21 suggests both that it will be difficult to robustly detect any human induced changes in observations of the NEP

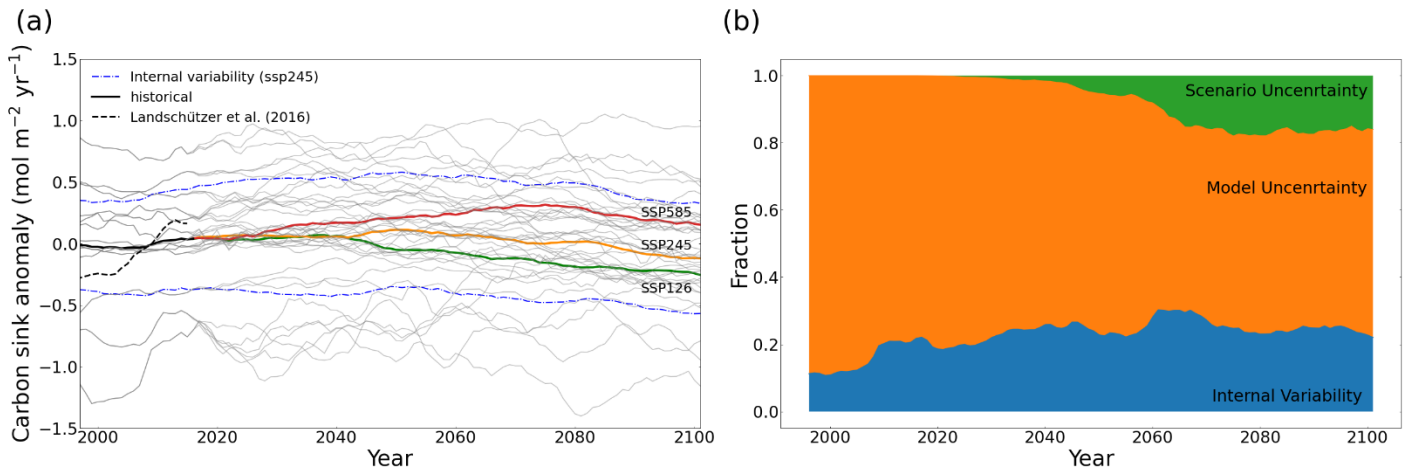

22 carbon sink, and that potential future differences relating to choice of mitigation scenarios will not be readily  
23 apparent in the NE Pacific carbon flux. This is true even for the high emission scenarios, because the anomalies  
24 are small regardless of scenario (Table 2). In the NW Atlantic however, the deviation across scenarios becomes  
25 larger than the internal variability in the early 2060s (Fig. 4c). The response of the region to climate change is  
26 dependent on the scenario (Table 2), or, in other words, the amount of carbon dioxide in the atmosphere. This is  
27 because the NW Atlantic is a hotspot where the air-sea flux actively responds to the atmospheric CO<sub>2</sub> concentration.  
28 The trend of the CMIP6 multi-model time-series over the historical period is statistically consistent (Santer et al.,  
29 2008) with that of the observation-based SOM-FFN product, and the multi-decadal variability is within the range  
30 of internal variability measured by the CanESM5 large-ensemble in both regions. We note that both of these regions  
31 are relatively well sampled, which may lead to more robust estimates of multi-decadal variability in the  
32 Landschützer et al. (2016) dataset, and better agreement with the models than seen at the global scale.

33  
34 Fractional estimates of each source of uncertainty vary with time and have different patterns for these two regions.  
35 Internal variability and model uncertainty in the NE Pacific and NW Atlantic are larger by an order of magnitude  
36 than at the global scale (Table 2). Over the period 1995-2020, model uncertainty is the dominant source of  
37 uncertainty in both the NE Pacific and NW Atlantic (80-90%), while the remainder is internal variability (Fig. 4bd).  
38 Internal variability explains around 25-30% of the total uncertainty in the NE Pacific throughout the century. In the  
39 NW Atlantic however, its share drops to 15% by the end of the century. The share attributable to internal variability  
40 is much larger during the 21<sup>st</sup> century in both regions compared to the global scale. Internal variability is larger in  
41 the NW Atlantic in an absolute sense (Table 2), but its share of the total uncertainty is larger in NE Pacific (Fig.  
42 4b). Overall, internal variability averaged over the scenarios shows a small increase, but no clear trend in time in  
43 both regions until the 2080-2100 period where it decreases, consistent with the global estimates. The dependence  
44 of internal variability on the scenario is an interesting result which requires further evaluations to understand the  
45 degree of dependence and the driving mechanisms of such changes with time based on scenario. We showed earlier  
46 that the NE Pacific scenarios do not differ much as the region is not a hotspot region - scenario uncertainty explains  
47 less than 20% of the total uncertainty at the end of the century in the NE Pacific. In the NW Atlantic, scenario  
48 uncertainty grows larger with time, becoming 45-50% of total uncertainty by the end of the century. In both  
49 regions, model uncertainty is the dominant source of uncertainty in all years.

66

67 **Table 2-** CMIP6 multi-model mean sink anomalies (with ranges in parentheses) relative to 1995-2015 mean (in mol-C m<sup>-2</sup>  
 68 yr<sup>-1</sup>) and internal variability (with model uncertainty in parentheses) for the three scenarios and their average values in NE  
 69 Pacific and NW Atlantic.

70  
71 The regional analysis shows that while uncertainty and its distribution among sources depends on the spatial scale  
72 of integration, the specific location also matters. Regional patterns of uncertainty broken down by the source are  
73 needed to clarify changes based on location. Consistent with the sink anomaly maps (Fig. 1), the regions that show  
74 highest uncertainty for any of the sources in the future, are the same regions that show the largest uncertainties in  
75 the historical period (Fig. 5). More importantly, the regions of largest future uptake uncertainty are highly correlated  
76 with the historical regions of largest uptake, as shown by the pattern correlation coefficients above each panel. This  
77 is a highly significant finding, because it suggests that knowledge of the modern day surface carbon flux anomaly  
78 provides us with information about future uptake uncertainty.

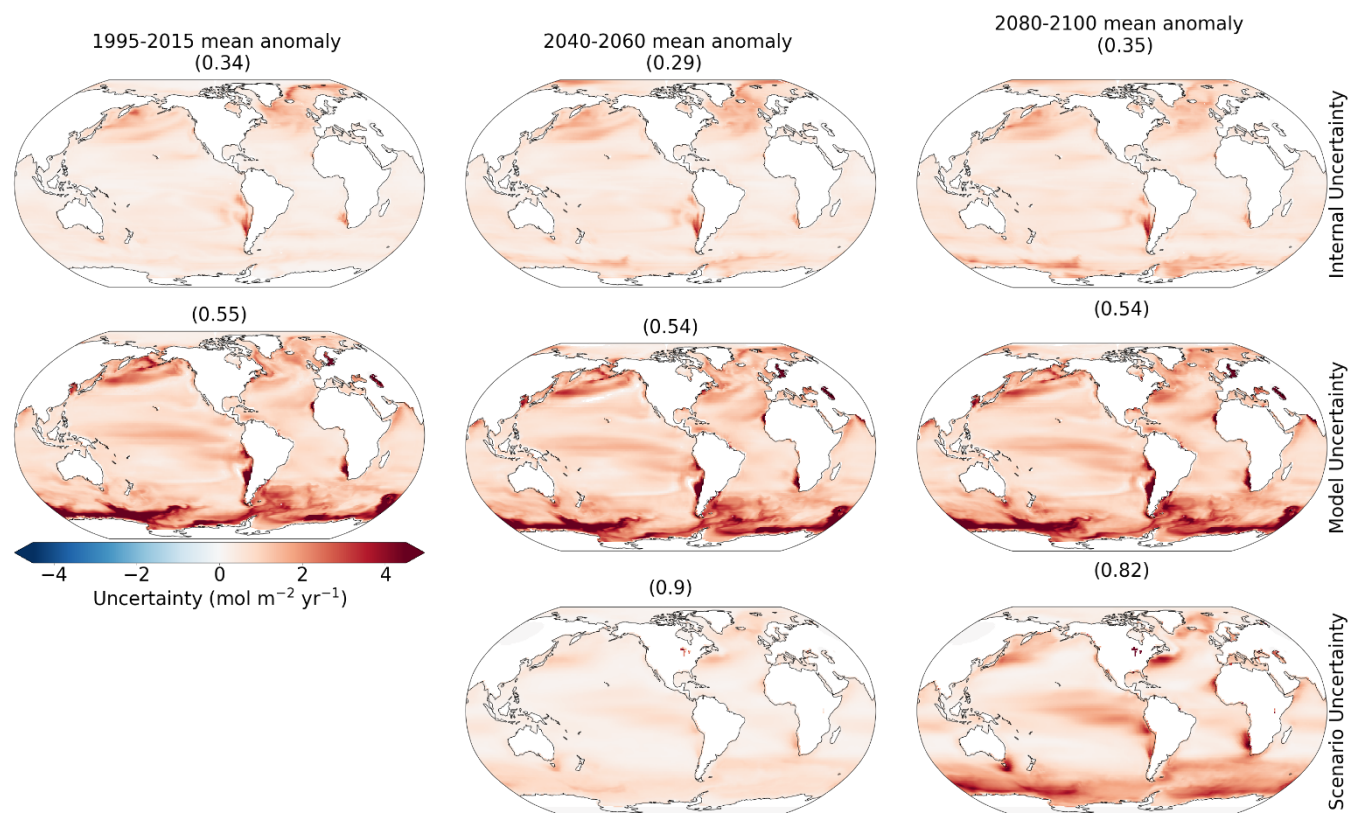

79  
80 The regions of high internal variability (eastern boundary upwelling regions, western boundary currents of the Gulf  
81 Stream and Kuroshio, their extensions, and the Southern Ocean) are mostly within hotspots but are not confined to  
82 them and do not include all of them. This lack of correspondence explains why the correlation coefficients are not  
83 high for internal variability. An increase in internal variability with time is seen mostly in regions such as the  
84 Southern Ocean, the Arctic Ocean, and boundaries of the gyre systems, while the rest of the ocean does not show  
85 a clear change. The maps in Figure 5 are averaged over the three scenarios, which masks the changes to some  
86 extent. However, we show in the Supplements (see section S2) that changes in the globally averaged internal  
87 variability with time are different for different scenarios. Model uncertainty is consistently highest in the hotspot  
88 regions, leading to stronger correlation with the anomaly maps of Fig. 1c. The model uncertainty is largest in the  
89 Southern Ocean, where the complex time-evolving nature of the sink varies on all time-scales. The importance of  
90 model uncertainty in the Southern Ocean provides a clear focal point for modelling centres to concentrate their  
91 efforts in reducing projection uncertainty. Atmospheric teleconnections might play an important role in generating  
92 the highly variable Southern Ocean carbon sink on decadal scales, and these are poorly constrained and represented  
93 by models (Gruber et al. 2019).

94  
95 Scenario uncertainty exhibits the largest change with time. This is by construction, meaning that scenarios are  
96 designed to deviate from each other as time goes forward. Importantly, the correlation coefficients are highest  
97 between scenario uncertainty and the current sink regions, indicating that the hotspot regions are the regions that  
98 show the largest divergence among scenarios, and that the sink in most other regions does respond as strongly to  
99 scenario differences. We showed an example of this earlier, where the timeseries of the multi-model signals for the  
100 three scenarios did not emerge out of internal variability in the NE Pacific by 2100, whereas they did for the hotspot

01 region of the NW Atlantic. This shows that, in these active hotspot regions, the sink evolves according to  
02 atmosphere CO<sub>2</sub> concentration via ocean processes that keep the surface ocean CO<sub>2</sub> out of equilibrium with the  
03 atmosphere. These uncertainties are central to the ability to detect human induced trends in observations of the  
04 surface ocean carbon flux, to which we now turn.

05

06

07 **Figure 5-** Sources of uncertainty averaged over the 20 year mean periods. The rows represent different sources as  
08 explained in the methods section at each grid cell. Columns represent different times: the recent (1995-2015), mid-  
09 century (2040-2060), and late-century (2080-2100) anomalies relative to the 1995-2015 mean. The numbers are  
10 correlation coefficients of each map with the 1995-2015 mean anomaly relative to the 1850-1900 mean (Fig. 1c).

11

### 12 3.4 Detectability

13 Detectability refers to the ability to robustly identify a forced signal, above and beyond the noise induced by internal  
14 climate variability. Understanding the regional differences, timescales, and scenario dependence in the detectability

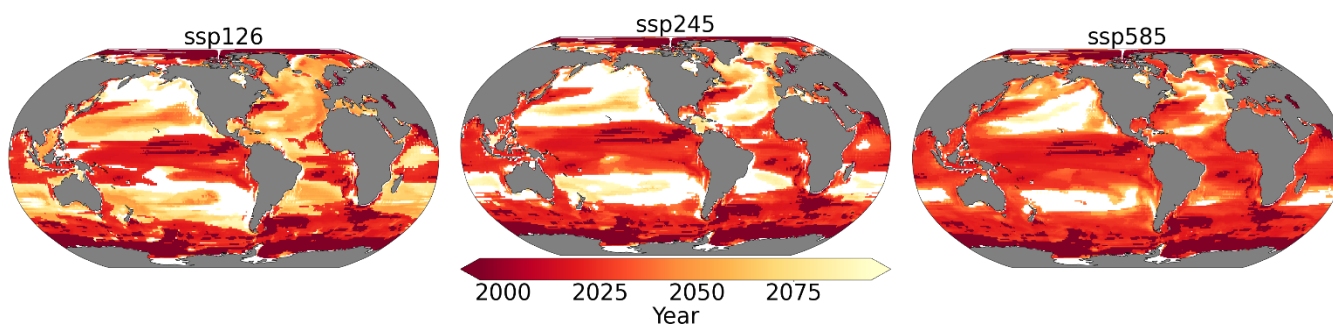

.15 of human induced trends in the ocean surface carbon flux is important for informing observational strategies that  
.16 aim to measure these changes.

.17  
.18 We measure the detectability of the CMIP6 multi-model ensemble mean ocean surface carbon flux anomaly using  
.19 the time of emergence at each grid point. We use this finest scale as it is the most applicable to observational  
.20 communities for sampling. The time of emergence is defined as the point at which the forced signal, given by the  
.21 multi-model ensemble mean flux anomaly, relative to 1995-2015, emerges from internal variability, given by the  
.22 CanESM5 SMILE.

.23  
.24 The signal in human induced surface ocean carbon flux emerges beyond the internal variability earlier in the hotspot  
.25 regions than anywhere else. This is evident in the Equatorial Pacific, Southern Ocean, the western boundary  
.26 currents of the gyre systems, and their extensions (Fig. 6). The fixed inactive regions, such as the centres of the  
.27 mid-latitude gyre systems and the NE Pacific, show late emergence times and, in some cases, no detectability of  
.28 the signal in any of the scenarios by 2100. This is consistent with the results from Sect. 3.3, in which we showed  
.29 that internal variability is a significant source throughout the century in the NE Pacific, with scenarios never  
.30 emerging out of the range of internal variability (Fig. 4a,b). This result argues for focusing observational efforts on  
.31 the hotspot regions in order to detect human influence on the ocean carbon sink. Meanwhile, they imply that  
.32 observational timeseries in quiescent regions, such as Ocean Station Papa in the NE Pacific, need to interpret any  
.33 observed trends with care, since internal variability tends to dominate over human induced trends.

.34  
.35  
.36

.37  
.38 **Figure 6-** Time of emergence of the multi-model mean anomaly under different scenarios. White regions indicate  
.39 where the anthropogenic signal cannot be detected even towards the end of the century.

40  
41 Previous studies have largely presented a single time of emergence; however, the time of emergence strongly  
42 depends on the future scenario. The time of emergence is earliest on average over the global ocean in ssp585, while  
43 it is later in ssp245, and later still in ssp126. The earlier times of emergence are largely due to the stronger signal  
44 in ssp585, and weaker in ssp245 and ssp126 (Fig. 2-a), consistent with the imposed changes in atmospheric CO<sub>2</sub>  
45 concentration. The exceptions are quiescent regions that show earlier detectability for ssp126 compared to other  
46 scenarios; these exceptions are associated with larger (but negative) anomalies in the latter half of the century under  
47 ssp126 which has negative emissions (compare panels d-f, and g-i on Fig. 1). Internal variability does evolve  
48 somewhat differently for each scenario, but this is secondary (Fig. B2). Our results suggest that under the rapidly  
49 rising atmospheric CO<sub>2</sub> concentrations seen in ssp585, the human signal in the ocean carbon sink will be detectable  
50 across much of the global ocean over the coming few decades. However, under strong mitigation scenarios, such  
51 as ssp126, early emergence will only occur in isolated regions.

#### 52 **4. Conclusions**

53 Ocean carbon uptake as a result of increasing atmospheric CO<sub>2</sub> concentration occurs mostly in a few hotspot  
54 regions. We analyze the results from the CMIP6 multi-model mean for the current state of the ocean (1995-2015),  
55 and the middle (2040-2060) and late (2080-2100) 21<sup>st</sup> century relative to the current state for three scenarios. We  
56 show that future changes in the sink mostly take place within the same historical hotspot regions. This result implies  
57 that known regions of high historical uptake, including the North Atlantic and Southern Ocean, are the same regions  
58 to prioritize for observing the future evolution of the sink.

59  
60 We show that the CMIP6 multi-model mean provides a consistent estimate of the spatial patterns of the sink, and  
61 the trend in the sink (globally), compared to the observation-based data product dataset of Landschützer et al.  
62 (2016). These results suggest the CMIP6 models are valid tools for understanding the past and future evolution of  
63 the ocean carbon sink, particularly at broad spatial scales. A notable area of disagreement is that the Landschützer  
64 et al. (2016) data shows larger decadal variability at the global scale than seen in any CMIP6 model. We argue the  
65 overestimation of internal variability by this dataset is a plausible explanation, since at the regional scale, there is  
66 no such disagreement. This is in agreement with Gloege et al. (2021) who showed that the SOM-FFN method  
67 overestimates the magnitude of decadal variability by 21% on the global scale.

68

.69 We have shown that the magnitude of uncertainty and its partitioning among different sources differs with scale  
.70 and location. On the global scale, scenario uncertainty is the largest source of uncertainty followed by model  
.71 uncertainty and internal variability. However, as the scales of integration (averaging) get finer, model and internal  
.72 variability become the dominant sources, respectively. Testing the results on two ocean basins of about the same  
.73 size, one in the NE Pacific and one in the NW Atlantic shows that - while consistent with the results of the scale  
.74 dependence analysis - the relative importance of the sources of uncertainty also differs with location. Notably, in  
.75 hotspot regions, such as the NW Atlantic, scenario uncertainty is large, whereas in more quiescent regions, such as  
.76 the NE Pacific, internal variability is more significant. The dependence of internal variability on the scenario with  
.77 time is another interesting finding that could be the subject of future studies for a better understanding of the driving  
.78 mechanism and the degree of dependence on the future emissions and/or concentrations.

.79  
.80 The patterns of high future CO<sub>2</sub> uptake uncertainty are highly correlated with the patterns of historical uptake. The  
.81 correlation coefficients are highest for scenario uncertainty, indicating that the hotspot regions have the potential  
.82 for the sink to evolve according to the atmospheric CO<sub>2</sub> concentration, while the rest of the ocean basins do not  
.83 respond strongly to changes in atmospheric CO<sub>2</sub> represented by the different scenarios. Our results here are  
.84 significant in that they show that regions of future uncertainty are largely associated with known regions of  
.85 significant historical uptake.

.86  
.87 Patterns seen in the time-of-emergence have implications for planning observational campaigns for detection of a  
.88 signal. Our results show that there should be caution taken in interpreting the observed changes in regions such as  
.89 NE Pacific (where active sampling is being done) associated with the late time of emergence of the signal from the  
.90 decadal (internal) variations. On the other hand, regions such as the Equatorial Pacific, the Gulf Stream and  
.91 Kuroshio and their extensions, and the Southern Ocean, should be the focus of consistent and expanded sampling  
.92 for detection of the forced signal. Additionally, the patterns in sources of uncertainty show that model uncertainty  
.93 is largest in the Southern Ocean, consistent with previous studies. The sink in the Southern Ocean is driven by  
.94 complex mechanisms involving coupled ocean-atmosphere-ice interactions that require better representation in  
.95 ocean biogeochemical models. If we wish to constrain and reduce future uncertainties in the ocean carbon sink, our  
.96 results provide a motivation to focus modelling as well as observational efforts on the known hotspot regions of  
.97 historical uptake.

.98

## 99 **Data Availability**

00 The data used in this study is part of the World Climate Research Programme's (WCRP) 6<sup>th</sup> Coupled Model  
01 Intercomparison Project (CMIP6) open access data. For details on accessibility see section S1 in the Supplements.  
02 The SOM-FFN data (Landschützer et al., 2017) from Landschützer (2016) can be accessed through the [National](#)  
03 [Oceanographic Data Center](#) (NODC, <https://www.nodc.noaa.gov/archive/arc0105/0160558/3.3/data/0-data/>)  
04 operated by the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

## 05 **Author Contribution**

06 Parsa Gooya conducted the formal analysis, visualization, and original draft preparation. Conceptualization, and  
07 methodology development and validation were a collaboration of the three authors, mainly developed by Parsa  
08 Gooya with contributions from Neil Swart in development, validation, and revision and Roberta Hamme in  
09 validation and revision. Neil Swart and Roberta Hamme provided supervision and reviewing and editing of the  
10 manuscript and methodology. Funding acquisition was carried out by Roberta Hamme.

## 11 **Competing of interest**

12 The authors declare that they have no conflict of interest.

## 13 **Acknowledgments**

14 This work was supported by the Marine Carbon Sink project, funded by the Natural Sciences and Engineering  
15 Research Council of Canada through the Advancing Climate Change Science in Canada program. We thank Jim  
16 Christian for helpful suggestions on a draft of the manuscript.
