15 **Abstract.** Lateral carbon transport from soils to the ocean through rivers has been acknowledged
16 as a key component of global carbon cycle, but is still neglected in most global land surface
17 models (LSMs). Fluvial transport of dissolved organic carbon (DOC) and CO₂ has been
18 implemented in the ORCHIDEE LSM, while erosion-induced delivery of sediment and
19 particulate organic carbon (POC) from land to river was implemented in another version of the
20 model. Based on these two developments, we take the final step towards the full representation
21 of biospheric carbon transport through the land-river continuum. The newly developed model,
22 called ORCHIDEE-C_{lateral}, simulates the complete lateral transport of water, sediment, POC,
23 DOC and CO₂ from land to sea through the river network, the deposition of sediment and POC in
24 the river channel and floodplains, and the decomposition of POC and DOC in transit. We
25 parameterized and evaluated ORCHIDEE-C_{lateral} using observation data in Europe. The model
26 explains 94%, 75% and 83% of the spatial variations of observed riverine water discharges,
27 bankfull water flows and riverine sediment discharges in Europe, respectively. The simulated
28 long-term average total organic carbon concentrations and DOC concentrations in river flows are
29 comparable to the observations in major European rivers, although our model generally
30 overestimates the seasonal variation of riverine organic carbon concentrations. Application of
31 ORCHIDEE-C_{lateral} for Europe reveals that the lateral carbon transfer affects land carbon
32 dynamics in multiple ways and omission of this process in LSMs may lead to an overestimation of
33 4.5% in the simulated annual net terrestrial carbon uptake over Europe. Overall, this study presents a
34 useful tool for simulating large scale lateral carbon transfer and for predicting the feedbacks
35 between lateral carbon transfer and future climate and land use changes.

36 **1 Introduction**

37 Lateral transfer of organic carbon along the land-river-ocean continuums, involving both spatial
38 redistribution of terrestrial organic carbon and the vertical land-atmosphere carbon exchange, has
39 been acknowledged as a key component of the global carbon cycle (Ciais et al., 2013; Ciais et
40 al., 2021; Drake et al., 2018; Regnier et al., 2013, 2022). Erosion of soils and the associated
41 organic carbon, but also leaching of soil dissolved organic carbon (DOC), represent a non-
42 negligible leak in the terrestrial carbon budget and a substantial source of allochthonous organic
43 carbon to inland waters and oceans (Battin et al., 2009; Cole et al., 2007; Raymond et al., 2013;
44 Regnier et al., 2013). As a result of soil aggregate breakdown and desorption, the accelerated
45 mineralization of these eroded and leached soil carbon loads leads to considerable CO₂ emission
46 to the atmosphere (Chappell et al., 2016; Lal, 2003; Van Hemelryck et al., 2011). Meanwhile, the
47 organic carbon that is redeposited and buried in floodplains and lakes might be preserved for a
48 long time, thus creating a CO₂ sink (Stallard, 1998; Van Oost et al., 2007; Wang et al., 2010;
49 Hoffmann, 2022). In addition, lateral redistribution of soil material can alter land-atmosphere
50 CO₂ fluxes indirectly by affecting soil nutrient availability, terrestrial vegetation productivity and
51 physiochemical properties of inland and coastal waters (Beusen et al., 2005; Vigiak et al., 2017).

52 Although the important role of lateral carbon transfer in the global carbon cycle has been widely
53 recognized, to date, the estimates of land carbon loss to inland waters, the fate of the terrestrial
54 organic carbon within inland waters, as well as the net effect of lateral carbon transfer on land-
55 atmosphere CO₂ fluxes remain largely uncertain (Berhe et al., 2007; Doetterl et al., 2016; Lal,
56 2003; Stallard, 1998; Wang et al., 2014b; Zhang et al., 2014). Existing estimates of global carbon
57 loss from soils to inland waters vary from 1.1 to 5.1 Pg (=10¹⁵ g) C per year (yr⁻¹) (Cole et al.,
58 2007; Drake et al., 2018), and the estimated net impact of global lateral carbon redistribution on
59 land-atmosphere carbon budget ranges from an uptake of atmospheric CO₂ by 1 Pg C yr⁻¹ to a
60 land CO₂ emission of 1 Pg C yr⁻¹ (Lal, 2003; Stallard, 1998; Van Oost et al., 2007; Wang et al.,
61 2017; Regnier et al., 2022). A reliable model which is able to explicitly simulate the lateral
62 carbon flux along the land-river continuum and also the interactions between these lateral fluxes
63 and the comprehensive terrestrial carbon cycle, would thus be necessary for projecting changes
64 in the global carbon cycle more accurately.

65 Global land surface models (LSMs) are important tools to simulate the feedbacks between
66 terrestrial carbon cycle, increasing atmospheric CO₂, and climate and land use change. However,
67 the lateral carbon transfer, especially for the particulate organic carbon (POC), is still missing or
68 incompletely represented in existing LSMs (Lauerwald et al., 2017; Lauerwald et al., 2020;
69 Lugato et al., 2016; Naipal et al., 2020; Nakhavali et al., 2021; Tian et al., 2015). It has been
70 hypothesized that the exclusion of lateral carbon transfer in LSMs implies a significant bias in
71 the simulated global land carbon budget (Ciais et al., 2013; Ciais et al., 2021; Janssens et al.,
72 2003). For instance, the study of Nakhavali et al. (2021) suggested that about 15% of the global
73 terrestrial net ecosystem production is exported to inland waters as leached DOC. Lauerwald et
74 al. (2020) showed that the omission of lateral DOC transfer in LSM might lead to significant
75 underestimation (8.6%) of the net uptake of atmospheric carbon in the Amazon basin while
76 terrestrial carbon storage changes in response to the increasing atmospheric CO₂ concentrations
77 were overestimated.

78 Over the past decade, a number of LSMs have been developed which represent leaching of DOC
79 from soils (Nakhavali et al. 2018, Kicklighter et al. 2013) or the full transport of DOC through
80 the land-river continuum (Lauerwald et al., 2017; Tian et al., 2015). However, the erosion-
81 induced transport of soil POC, which has also been reported to be able to affect the carbon
82 balance of terrestrial ecosystems strongly (Lal., 2003; Van Oost et al., 2007; Tian et al., 2015), is
83 still not or poorly represented in LSMs. The explicit simulation of the complete transport process
84 of POC at large spatial scales is still a major challenge, due to the complexity of the processes
85 involved, including erosion-induced sediment and POC delivery to rivers, deposition of
86 sediment and POC in river channels and floodplains, re-detachment of the previously deposited
87 sediments and POC, decomposition and transformation of POC in riverine and flooding waters,
88 as well as the changes of soil profile caused by erosion and deposition (Doetterl et al., 2016;
89 Naipal et al., 2020; Zhang et al., 2020).

90 Several recent model developments have led to the implementation of the lateral transfer of POC
91 in large-scale LSMs. Despite this, there are still some inevitable limitations in these
92 implementations. The Dynamic Land Ecosystem Model (DLEM v2.0, Tian et al., 2015) is able
93 to simulate the erosion-induced POC loss from soil to river and the transport and decomposition
94 of POC in river networks. However, it does not represent the POC deposition in floodplains, nor

95 the impacts of soil erosion and floodplain deposition on the vertical profiles of soil organic
96 carbon (SOC). The Carbon Erosion DYNAMics model (CE-DYNAM, Naipal et al., 2020)
97 simulates erosion of SOC and its re-deposition on the toe-slope or floodplains, transport of POC
98 along river channels, as well as the impact on SOC dynamics at the eroding and deposition sites.
99 However, running at annual time scale, it mostly addresses the centennial timescale and does not
100 represent deposition and decomposition of POC in river channels. Moreover, CE-DYNAM was
101 only applied over the Rhine catchment and has not been fully coupled into a land surface model,
102 therefore excluding the feedbacks of soil erosion on the fully coupled land and aquatic carbon
103 cycles. There are of course more dedicated hydrology and soil erosion models that explicitly
104 simulate the complete transport, deposition and decomposition processes of POC in small river
105 basins (e.g. Jetten et al., 2003; Nearing et al., 1989; Neitsch et al., 2011). However, it is difficult
106 to apply these models at large spatial scales (e.g. continental or global scale) due to the limited
107 availability of forcing data (e.g. geometric attributes of river channel), suitable model
108 parameterization and computational capacity. Moreover, these models have limited capability of
109 representing the full terrestrial C cycle in response to climate change, increasing atmospheric
110 CO₂ and land use change. Therefore, basin-scale models are not an option to assess the impact of
111 soil erosion on the large-scale terrestrial C budget in response to global changes.

112 Here we describe the development, application and evaluation of a new branch of the
113 ORCHIDEE LSM (Krinner et al., 2005), hereafter ORCHIDEE-C_{lateral}, that can be used to
114 simulate the complete lateral transfer processes of water, sediment, POC and DOC along the
115 land-river-ocean continuum at large spatial scale (e.g. continental and global scale). In previous
116 studies, the leaching and fluvial transfer of DOC and the erosion-induced delivery of sediment
117 and POC from upland soil to river network have been implemented in two different branches of
118 the ORCHIDEE LSM (i.e. ORCHILEAK (Lauerwald et al., 2017) and ORCHIDEE-MUSLE
119 (Zhang et al., 2020)). For this new branch, we first merged these two branches, and subsequently
120 implemented the fluvial transfer of sediment and POC in the coupled model. ORCHIDEE-C_{lateral}
121 is calibrated and evaluated using observation data of runoff, bankfull flow, and riverine loads and
122 concentrations of sediment, POC and DOC across Europe. By applying the calibrated model at
123 European scale, we estimate the magnitude and spatial distribution of the lateral carbon transfer
124 in European catchments during the period 1901-2014, as well as the potential impacts of lateral
125 carbon transfer on the land carbon balance. Comparing simulations results to those of an

126 alternative simulation run with lateral displacement of C deactivated, we finally quantify the
127 biases in simulated land C budgets that arise ignoring the lateral transfers of C along the land-
128 river continuum.

129

130 **2 Model development and evaluation**

131 **2.1 ORCHIDEE land surface model**

132 The ORCHIDEE LSM comprehensively simulates the cycling of energy, water and carbon in
133 terrestrial ecosystems (Krinner et al., 2005). The hydrological processes (e.g. rainfall
134 interception, evapotranspiration and soil water dynamics) and plant photosynthesis in
135 ORCHIDEE are simulated at a time step of 30 minutes. The carbon cycle processes (e.g.
136 maintenance and growth respiration, carbon allocation, litter decomposition, SOC dynamics,
137 plant phenology and mortality) are simulated at daily time step. In its default configuration,
138 ORCHIDEE represents 13 land cover types, with one for bare soil and 12 for lands covered by
139 vegetation (eight types of forests, two types of grasslands, two types of croplands). Given
140 appropriate land cover maps and parametrization, the number of PFTs to be represented can
141 however be adapted (Zhang et al., 2020).

142 Our previous implementations of lateral DOC transfer (Lauerwald et al., 2017) and of POC
143 delivery from upland to river network (Zhang et al., 2020) were both based on the ORCHIDEE
144 branch ORCHIDEE-SOM (Camino-Serrano et al., 2018, Fig. S1), which provides a depth-
145 dependent description of the water and carbon dynamics in soil column. In specific, the vertical
146 soil profile in ORCHIDEE-SOM is described by an 11-layer discretization of a 2 m soil column
147 (Camino-Serrano et al., 2018). Water flows between adjacent soil layers are simulated using the
148 Fokker–Planck equation that resolves water diffusion in non-saturated conditions (Campoy et al.,
149 2013; Guimberteau et al., 2018). Free gravitational drainage occurs in the lowest soil layer when
150 actual soil water content is higher than the residual water content (Campoy et al., 2013).
151 Following the CENTURY model (Parton et al., 1988), ORCHIDEE-SOM represents two litter
152 pools (metabolic and structural) and three SOC pools (active, slow and passive) that differ in
153 their respective turnover times. The decomposition of each carbon pool is calculated by first
154 order kinetics based on the corresponding turnover time, soil moisture and temperature as

155 controlling factors, as well as the priming effects of fresh organic matter (Guenet et al., 2018;
156 Guenet et al., 2016). Soil DOC is represented by a labile and a refractory DOC pools, with a high
157 and low turnover rate, respectively. Each DOC pool may be in the soil solution or adsorbed on
158 the mineral matrix. The products of litter and SOC decomposition enter the free DOC pool,
159 which in turn is decomposed following first order kinetics (Kalbitz et al., 2003) and returns back
160 to SOC. Adsorption and desorption of DOC follows an equilibrium distribution coefficient
161 calculated from soil clay and pH. Free DOC can be transported with the water flux simulated by
162 the soil hydrological module of ORCHIDEE. However, DOC adsorbed to soil minerals can
163 neither be decomposed nor transported (Camino-Serrano et al., 2018). All the described
164 processes occur within each soil layer. At each time step, “the flux of DOC leaving the soil is
165 calculated by multiplying DOC concentrations in soil solution with the runoff (surface layer) and
166 drainage (bottom layer) flux simulated by the hydrological module” (Camino-Serrano et al.,
167 2018, p. 939). More detailed information about the simulation of soil hydrological and
168 biogeochemical processes in ORCHIDEE-SOM can be found in Guenet et al. (2016) and
169 Camino-Serrano et al. (2018).

170 **2.1.1 Lateral transfer of DOC and CO₂**

171 Lateral transfer of DOC and dissolved CO₂ from land to ocean through river network has been
172 implemented in the ORCHILEAK (Lauerwald et al., 2017), an ORCHIDEE branch developed
173 from ORCHIDEE-SOM (Fig. S1). The method used in ORCHILEAK to simulate the adsorption,
174 desorption, production, consumption and transport of DOC within the soil column, as well as
175 DOC export from the soil column with surface runoff and drainage is similar to that used in
176 ORCHIDEE-SOM. Besides the decomposition of SOC and litter, ORCHILEAK also represents
177 the contribution of wet and dry deposition to soil DOC via throughfall. The direct DOC input
178 from rainfall to aquatic DOC pools is simulated based on the DOC concentration in rainfall and
179 the area fraction of stream and flooding waters in each basin (Table 1). Note that the maximum
180 area fractions of river surface and floodplain in each basin (i.e. each 0.5°×0.5° grid cell in this
181 study) are derived from high-resolution topographic data (Table 1). As it is difficult to explicitly
182 represent all real river channels in a global land surface model (due to the limit of computing
183 efficiency of current computers), we assume that there is one virtual river channel in each

184 0.5°×0.5° pixel. The surface area of this virtual river is the sum of all real rivers and the flow
 185 direction of this virtual is assumed to be same to the largest real river (Lauerwald et al., 2015).

186 Simulation of the lateral transfer of DOC and CO₂ in river networks, i.e. the transfer of DOC and
 187 CO₂ from one basin to another based on the stream flow directions obtained from a forcing file
 188 (0.5°, Table 1), follows the routing scheme of water (Guimberteau et al., 2012). For each basin
 189 with floodplain (defined by forcing data), bankfull flow occurs when stream volume in the river
 190 channel exceeds a threshold prescribed by the forcing file (Table 1). DOC and CO₂ in flooding
 191 waters can enter into soil DOC and CO₂ pools along with the flooding water infiltrated into soil.
 192 The infiltration rate of flooding water depends on soil properties and soil water content, but does
 193 not depend on vegetation cover. On the contrary, DOC and CO₂ originated from the
 194 decomposition of submerged litter and SOC in the floodplains are added to the overlying
 195 flooding waters. Note that the turnover times of litter and SOC under flooding waters are
 196 assumed to be three times of the litter and SOC turnover times in upland soil (Reddy & Patrick
 197 Jr, 1975; Neckles & Neill, 1994; Lauerwald et al., 2017). After removing the infiltrated and
 198 evaporated water, the amount of the remaining flooding water, as well as the DOC and dissolved
 199 CO₂ returning to river channel at the end of each day is calculated based on a time constant of
 200 flooding water (= 4.0 days, d’Orgeval et al., 2008) modified by a basin-specific topographic
 201 index (f_{topo} , unitless) (Lauerwald et al., 2017).

202

203 **Table 1.** List of forcing data needed to run ORCHIDEE-C_{lateral} and the data used to evaluate the
 204 simulation results. S_{res} and T_{res} are the spatial and temporal resolution of the forcing data,
 205 respectively.

	Data	S_{res}	T_{res}	Data source
Forcing	Climatic forcing data (precipitation, temperature, incoming shortwave/longwave radiation, air pressure, wind speed, relative humidity)	0.5°	3 hour	GSWP3 database (Dirmeyerm et al., 2006)

215

216 Decomposition of DOC in stream and flooding waters is calculated at daily time step based on
 217 the prescribed turnover times of labile (2 days) and refractory (80 days) DOC in waters (when
 218 temperature is 28 °C) and a temperature factor obtained from Hanson et al. (2011). CO₂ evasion
 219 in inland waters is simulated using a much finer integration time step of 6 minutes. The CO₂
 220 partial pressures ($p\text{CO}_2$) in water column is first calculated based on the temperature-dependent
 221 solubility of CO₂ and the concentration of dissolved CO₂ (Telmer and Veizer, 1999). Then the
 222 CO₂ evasion is calculated based on the gas exchange velocity, the water–air gradient in $p\text{CO}_2$,
 223 and the surface water area available for gas exchange (Lauerwald et al., 2017). The effect of
 224 wind speed on CO₂ evasion is not represented in the current version of ORCHILEAK. In
 225 addition, swamp and wetland are represented in the routing scheme of ORCHILEAK. More
 226 detailed descriptions can be found in Lauerwald et al. (2017).

227 **2.1.2 Sediment and particulate organic carbon delivery from upland soil to river network**

228 To give an accurate simulation of sediment delivery from uplands to river network and maintain
 229 computational efficiency, an upscaling scheme which integrates information from high-resolution (3")
 230 topographic and soil erodibility data into a LSM forcing file at 0.5° spatial resolution, has been introduced
 231 (see details in Zhang et al., 2020, Fig. 1). With this upscaling scheme, the erosion-induced sediment and
 232 POC delivery from upland soils to the river network, as well as the changes in SOC profiles due to soil
 233 erosion had already been implemented in ORCHIDEE-MUSLE (Zhang et al., 2020). The sediment
 234 delivery from small headwater basins (which are basins without perennial stream and are extracted from
 235 high-resolution (e.g. 3") digital elevation model (DEM) data, Figs. 1a&d) to the river network (i.e. gross
 236 upland soil erosion – sediment deposition within headwater basins) is simulated using the Modified
 237 Universal Soil Loss Equation model (MUSLE, Williams, 1975). As introduced in Zhang et al. (2020),
 238 “the daily sediment delivery rate from each headwater basin (S_{i_ref} , Mg day⁻¹ basin⁻¹) is first calculated for
 239 a given set of reference runoff and vegetation cover conditions (Fig. 1e):

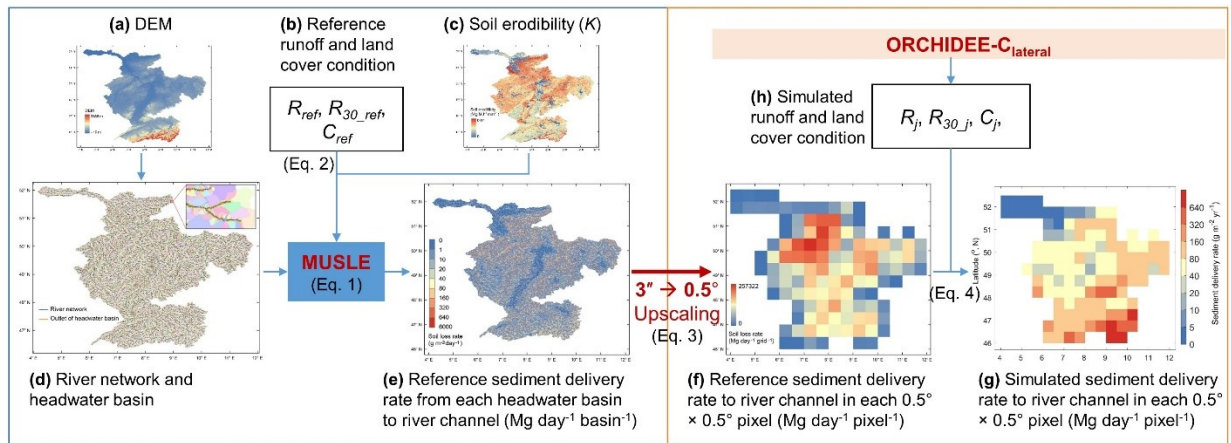

$$240 \quad S_{i_ref} = a(Q_{i_ref} q_{i_ref})^b K_i L S_i C_{ref} P_{ref} \quad (1)$$

241 where Q_{i_ref} is the total water discharge (m³ day⁻¹) at the outlet of headwater basin i for the daily
 242 reference runoff condition (R_{ref}) of 10 mm day⁻¹ (see Table S1 for the definitions of all
 243 abbreviations used in this study). In Eq. 1, q_{i_ref} is the daily peak flow rate (m³ s⁻¹) at the
 244 headwater basin outlet under the assumed reference runoff condition. Similar to the SWAT
 245 model (Soil and Water Assessment Tool, Neitsch et al., 2011), q_{i_ref} was calculated from the

246 reference maximum 30-minutes runoff (= 1 mm 30-minutes⁻¹) depth and drainage area (DA_i , m²)
 247 according to the following equation:

$$248 \quad q_{i_ref} = \frac{R_{30_ref}}{30 \times 60} \left(DA_i^{(d DA_i^c)} \right) 1000 \quad (2)$$

249 where R_{30_ref} (= 1 mm 30-minutes⁻¹) is the assumed daily maximum 30-minutes runoff". The
 250 coefficients a and b in Eq. 1 and c and d in Eq. 2 need to be calibrated (see section 2.3 and Table
 251 2). In Eq. 1, the term LS_i is the combined dimensionless slope length and steepness factor
 252 calculated based on the DA_i and the average slope steepness (extracted from DEM) of headwater
 253 basin i (Moore and Wilson, 1992). C_{ref} (0-1, dimensionless) in Eq. 1 represents the cover
 254 management factor which depends on vegetation cover and storage of plant debris (see below).
 255 The value of C_{ref} is set to 0.1 for the reference state. The soil erodibility factor K_i (Mg MJ⁻¹ mm⁻¹)
 256 is calculated using the method of the EPIC model (Sharpley and Williams, 1990) based on
 257 SOC and soil texture data obtained from the GSDE database (Table 1). The term P_{ref} (0-1,
 258 dimensionless) in Eq. 1 is a factor representing erosion control practices. It was set to 1, as we
 259 did not consider the impacts of soil conservation practices in reducing soil erosion rate. Note that
 260 it does not matter which value is chosen for the R_{ref} , R_{30_ref} and C_{ref} as long as they are used
 261 consistently throughout a study.

262
 263 **Figure 1** Upscaling scheme used in ORCHIDEE-MUSLE (Zhang et al., 2020) and ORCHIDEE-
 264 $C_{lateral}$ for calculating the sediment delivery rate from headwater basins to river networks.

265 MUSLE is the Modified Universal Soil Loss Equation; DEM is the digital elevation model (m);
 266 K is the soil erodibility factor (Mg MJ⁻¹ mm⁻¹); R_{ref} is the assumed reference daily runoff depth
 267 (= 10 mm day⁻¹); R_{30_ref} is the assumed reference maximum 30-minutes runoff depth (= 1 mm

268 30-minutes⁻¹); C_{ref} (= 0.1, dimensionless) is the assumed reference cover management factor;
 269 R_{iday} , R_{30_iday} and C_{iday} are the simulated daily total runoff depth, daily maximum 30-minutes
 270 runoff depth and daily cover management factor, respectively. This figure is adapted from the
 271 Fig. 1 in Zhang et al. (2020).

272

273 For the use of these reference sediment delivery estimates in ORCHIDEE-C_{lateral}, the values were
 274 first calculated for each headwater basin derived from high resolution geodata (Fig. 1e), then
 275 aggregated to 0.5° grid cells (Fig. 1f) – the scale used in our simulations and required to maintain
 276 computational efficiency (also limited by the availability of climate and land cover forcing data).

277 This aggregated dataset is then used to force the simulation of the actual daily sediment delivery
 278 (S_j , g day⁻¹ grid⁻¹) in ORCHIDEE-C_{lateral}, simply based on the estimated reference sediment
 279 delivery rates of Eq. (1) and on the ratios between actual runoff and land cover conditions and
 280 the assumed reference conditions used to create that forcing file (Eq. 4, Fig. 1g).

$$281 \quad S_{ref} = \sum_{i=1}^n (S_{i_ref}) \times 10^6 \quad (3)$$

$$282 \quad S_j = S_{ref} \left(\frac{R_j R_{30_j}}{R_{ref} R_{30_ref}} \right)^b \frac{C_j}{C_{ref}} \quad (4)$$

283 where R_j (mm day⁻¹) is the total surface runoff on day j simulated by the hydrological module or
 284 ORCHIDEE-MUSLE at 0.5° spatial resolution every 30 minutes. R_{30_j} (mm 30-min⁻¹) is the
 285 maximum value of the 48 half-hour runoffs in each day. C_j (0-1, unitless) is the daily actual
 286 cover management factor, calculated based on the fraction of surface vegetation cover, the
 287 amount of litter stock and the biomass of living roots in each PFT within each 0.5°×0.5° grid
 288 cell. R_{ref} , R_{30_ref} , C_{ref} and P_{ref} are the reference values used to estimate the reference sediment
 289 delivery rates as describe above.

290 Daily POC delivery to river headstream in each 0.5° grid cell is finally simulated based on the
 291 sediment delivery rate and the average SOC concentration of surface soil layers (0-20 cm). We
 292 assumed that litter cannot be eroded and transported to the river network, however, it can affect
 293 soil erosion rate through the cover management factor of the MUSLE model (denoted by C_j , Eq.
 294 4). The vertical SOC profile is updated every day based on the average depth of eroded soil for

295 each PFT in each 0.5° grid cell of ORCHIDEE. For more detailed description of the
 296 ORCHIDEE-MUSLE, we refer to Zhang et al. (2020).

297

298 2.2 Sediment and POC transport in inland water network

299 Through the merge of the model branches ORCHILEAK and ORCHIDEE-MUSLE, the new
 300 branch ORCHIDEE-C_{lateral} combines the novel features of both sources (DOC and POC)
 301 described above. The development of ORCHIDEE-C_{lateral} is complemented by a representation of
 302 the sediment and POC transport through the river network that is completely novel and described
 303 below.

304 2.2.1 Sediment transport

305

306 **Figure 2** Simulated lateral transfer processes of water, sediment and carbon (POC, DOC and
 307 CO₂) in ORCHIDEE-C_{lateral} (a) and a schematic plot for the reservoirs and flows of water,
 308 sediment and carbon represented in the routing module of ORCHIDEE-C_{lateral} (b). S_{soil} is the soil
 309 pool. S_{rivbed} is the sediment (also POC) deposited on the river bed. S_{fast}, S_{slow}, S_{riv} and S_{fld} are the
 310 ‘fast’, ‘slow’, stream and flooding water reservoir, respectively. F_{RO} and F_{DR} are the surface
 311 runoff and belowground drainage, respectively. F_{Fout} and F_{Sout} are the flows from fast and slow
 312 reservoir to the stream reservoir, respectively. F_{up2riv} and F_{down2riv} are the upstream inputs and
 313 downstream outputs, respectively. F_{riv2fld} is the outputs from river stream to the flooding
 314 reservoir. F_{fld2riv} is the return flow from flooding reservoir to stream reservoir. F_{bed2fld} is the
 315 transform from deposited sediment in river bed to floodplain soil. F_{bero} is bank erosion. F_{rd} and
 316 F_{rero} are the deposition and re-detachment of sediment and POC in river channel, respectively.
 317 F_{sub} is the flux of DOC and CO₂ from floodplain soil (originated from the decomposition of
 318 submerged litter and soil carbon) to the overlying flooding water. F_{fd} is the deposition of
 319 sediment and POC and the infiltration of water and DOC. F_D is the wet and dry deposition of
 320 DOC from atmosphere and plant canopy. DOC_l and DOC_r are the labile and refractory DOC
 321 pool, respectively. POC_a, POC_s and POC_p are the active, slow and passive POC pool,
 322 respectively.

323 Simulation of sediment transport through the river network basically follows the routing scheme
 324 of surface water and DOC of ORCHILEAK (Fig. 2). Along with surface runoff (F_{RO_h2o} , m³ day⁻¹),
 325 the sediment delivery (F_{RO_sed} , g day⁻¹) from uplands in each basin (i.e. each 0.5° grid cell in
 326 the case of this study) initially feeds an aboveground water reservoir (S_{fast_h2o} , m³) with a so-
 327 called fast water residence time. From this fast water reservoir, a delayed outflow feeds into the
 328 so-called stream reservoir (S_{riv} , m³, Fig. 2b). Daily water (F_{Fout_h2o} , m³ day⁻¹) and sediment
 329 (F_{Fout_sed} , g day⁻¹) flows from fast water reservoir to stream reservoir are calculated from a grid
 330 cell-specific topographic index f_{topo} (unitless, Vörösmarty et al., 2000) extracted from a forcing
 331 file (Table 1) and a reservoir-specific factor τ which translates f_{topo} into a water residence time of
 332 each reservoir (Eqs. 5, 6). Following Guimberteau et al. (2012), the τ of the fast water reservoir
 333 (τ_{fast}) is set to 3.0 days. As the sediment delivery calculated from MUSLE is the net soil loss
 334 from headwater basins (gross soil erosion – soil deposition within headwater basins), we
 335 assumed that there is no sediment deposition in the fast reservoir, and that all of the sediment in
 336 the fast reservoir enters the stream reservoir. In addition, only the surface runoff causes soil

337 erosion. The belowground drainage (F_{DR_h2o} , $m^3 \text{ day}^{-1}$) only transports DOC and dissolved CO_2
 338 to the stream reservoir (Fig. 2b).

$$339 \quad F_{Fout_h2o} = \frac{S_{fast_h2o}}{\tau_{fast} f_{topo}} \quad (5)$$

$$340 \quad F_{Fout_sed} = \frac{S_{fast_sed}}{\tau_{fast} f_{topo}} \quad (6)$$

341 The budget of the suspended sediment in the stream (S_{riv_sed} , g) is determined by F_{out_sed} , the
 342 upstream sediment input (F_{up2riv_sed} , $g \text{ day}^{-1}$), the sediment input by flooding water returning to
 343 the river ($F_{fld2riv_sed}$, $g \text{ day}^{-1}$), the re-detachment of the previously deposited sediment in the river
 344 bed (F_{rero_sed} , $g \text{ day}^{-1}$), the bank erosion (F_{bero_sed} , $g \text{ day}^{-1}$), the sediment deposition in the river
 345 bed (F_{rd_sed} , $g \text{ day}^{-1}$) and the sediment transported to downstream river stretches ($F_{down2riv_sed}$, g
 346 day^{-1}) and, occasionally, floodplains ($F_{riv2fld_sed}$, $g \text{ day}^{-1}$) (Eq. 7).

$$347 \quad \frac{dS_{riv_sed}}{dt} = F_{Fout_sed} + F_{up2riv_sed} + F_{fld2riv_sed} + F_{rero_sed} + F_{bero_sed} - F_{rd_sed} - F_{down2riv_sed} - F_{riv2fld_sed} \quad (7)$$

348 Sediment transport capacity (TC, $g \text{ m}^{-3}$) is defined as the maximum concentration of suspended
 349 sediment that a given flow rate can carry. TC and the flow rate determine the amount of sediment
 350 that can be transported to the downstream grid cell (e.g. $F_{down2riv_sed}$, $F_{riv2fld_sed}$). Suspended
 351 sediment loads that are in excess to maximum possible amount of transported sediment will
 352 deposit on the river bed (F_{rd_sed}). If sediment loads are below that maximum possible amount,
 353 erosion of the river bed (F_{rero_sed}) or river bank (F_{bero_sed}) takes place (Arnold et al., 1995;
 354 Nearing et al., 1989; Neitsch et al., 2011).

355 In this study, we used an empirical equation adapted from the WBMsed model, which has been
 356 proven effective in simulating the suspended sediment discharges in global large rivers (Cohen et
 357 al., 2014), to estimate the TC of suspended sediment concentration in stream flow ($g \text{ m}^{-3}$):

$$358 \quad TC = \frac{\omega q_{ave}^{0.3} A^{0.5} \left(\frac{q_{iday}}{q_{ave}}\right)^{e_1} (24 \times 60 \times 60)}{F_{down2riv_h2o}} \quad (8)$$

$$359 \quad e_1 = 1.5 - \max(0.8, 0.145 \log_{10} DA) \quad (9)$$

360 where ω is the coefficient of proportionality, q_{ave} ($m^3 \text{ s}^{-1}$) is long-term average stream flow rate
 361 obtained from an historical simulation by ORCHILEAK (Table 1), q_j ($m^3 \text{ s}^{-1}$) is stream flow rate
 362 on day j , e_1 is an exponent depending on the upstream drainage area (DA , m^2), $F_{down2riv_h2o}$ (m^3

363 day⁻¹) is the daily downstream water discharge from the stream reservoir. In the stream reservoir
 364 of each basin, net deposition occurs when TC is smaller than the concentration of suspended
 365 sediment, and the daily deposited sediment (F_{rd_sed} , g day⁻¹) is calculated based on the surplus of
 366 the suspended sediment:

$$367 \quad F_{rd_sed} = c_{rivdep}(S_{riv_sed} - TC S_{riv_h2o}) \quad (10)$$

368 where c_{rivdep} (0-1, unitless) is the daily deposited fraction of the sediment surplus. Net erosion of
 369 the previously deposited sediment in river bed (S_{rivbed_sed} , Fig. 2) or the river bank occurs when
 370 TC is larger than the concentration of suspended sediment. We assumed that the erosion of river
 371 bank occurs only after all of the S_{rivbed_sed} has been eroded. Thus the daily erosion rate (F_{rero_sed} , g
 372 day⁻¹) in river channel is calculated as:

$$373 \quad F_{rero_sed} = \begin{cases} c_{ebed}(TC S_{riv_h2o} - S_{riv_sed}), & c_{ebed}(TC S_{riv_h2o} - S_{riv_sed}) \leq S_{rivbed_sed} \\ S_{rivbed_sed} + c_{ebank}(TC S_{riv_h2o} - S_{riv_sed} - S_{rivbed_sed}), & c_{ebed}(TC S_{riv_h2o} - S_{riv_sed}) > S_{rivbed_sed} \end{cases} \quad (11)$$

374 where c_{ebed} (0-1, unitless) and c_{ebank} (0-1, unitless) are the fraction of sediment deficit that can be
 375 complemented by erosion of river bed and bank, respectively. After updating the S_{riv_sed} based on
 376 the F_{rd_sed} or F_{rero_sed} , the sediment discharge to downstream basin ($F_{down2riv_sed}$, g day⁻¹) is
 377 calculated based on the ratio of downstream water discharge to the total stream reservoir:

$$378 \quad F_{down2riv_sed} = (S_{riv_sed} - F_{rd_sed} + F_{rero_sed}) \frac{F_{down2riv_h2o}}{S_{riv_sh2o}} \quad (12)$$

379 In each basin, the bankfull flow occurs when S_{riv_h2o} exceeds the maximum water storage of river
 380 channel (S_{rivmax} , g), which is defined by a forcing file (Table 1). Sediment flow from stream to
 381 floodplain ($F_{riv2fld_sed}$, g day⁻¹) follows the flooding water, and it is calculated as:

$$382 \quad F_{riv2fld_sed} = (S_{riv_sed} - F_{rd_sed} + F_{rero_sed}) \frac{F_{riv2fld_h2o}}{S_{riv_sh2o}} \quad (13)$$

$$383 \quad F_{riv2fld_h2o} = (S_{riv_h2o} - F_{down2riv_h2o} - S_{rivmax}) \frac{f_{A_fld}}{f_{A_fld} + f_{A_riv}} \quad (14)$$

384 where f_{A_fld} (0-1, unitless) and f_{A_riv} (0-1, unitless) is the fraction of floodplain area and river
 385 surface area in each basin, respectively. Following the routing scheme of ORCHILEAK, the
 386 bankfull flow of a specific basin is assumed to enter the floodplain in the neighbouring
 387 downstream basin instead of the basin where it originates.

388 The sediment balance in flooding reservoir (S_{fld_sed} , g) is controlled by sediment input from the
 389 upstream basins ($F_{riv2fld_sed}$, g day⁻¹), the sediment flowing back to the stream reservoir ($F_{fld2riv_sed}$,
 390 g day⁻¹) and the sediment deposition (F_{fd_sed} , g day⁻¹) (Fig. 2):

$$391 \quad \frac{dS_{fld_sed}}{dt} = F_{riv2fld_sed} - F_{fld2riv_sed} - F_{fd_sed} \quad (15)$$

392 Sediment deposition in floodplain is calculated as the sum of a natural deposition and the
 393 deposition due to evaporation (E_{h2o} , m³ day⁻¹) and infiltration (I_{h2o} , m³ day⁻¹) of the flooding
 394 waters:

$$395 \quad F_{fd_sed} = c_{flddep} S_{fld_sed} + S_{fld_sed} \frac{E_{h2o} + I_{h2o}}{S_{fld_h2o}} \quad (16)$$

396 where c_{flddep} (0-1, unitless) is the daily deposited fraction of the suspended sediment in flooding
 397 waters. After removing the deposited sediment from S_{fld_sed} , $F_{fld2riv_sed}$ is calculated based on the
 398 ratio of ratio of $F_{fld2riv_h2o}$ to the total flooding reservoir:

$$399 \quad F_{fld2riv_sed} = S_{fld_sed} \frac{F_{fld2riv_h2o}}{S_{fld_h2o} - E_{h2o} - I_{h2o}} \quad (17)$$

400

$$401 \quad F_{fld2riv_h2o} = \frac{S_{fld_h2o} - E_{h2o} - I_{h2o}}{\tau_{flood} f_{topo}} \quad (18)$$

402 where τ_{flood} is a factor which translates f_{topo} (Table 1) into a water residence time of the flooding
 403 reservoir. Same to ORCHILEAK, it is set to 1.4 (day m⁻²) in this study.

404 Note that as the upland soil in ORCHIDEE is composed of clay, silt and sand particles, so that
 405 the dynamics of clay-, silt- and sand-sediment in inland waters are simulated separately. To
 406 represent the selective transport of clay-, silt- and sand-sediment, the model parameter ω (Eq. 8)
 407 and c_{rivdep} (Eq. 10) are set to different values when calculating the sediment transport capacity
 408 and the deposition of surplus suspended sediment for different particle sizes (Table 2).

409 Moreover, as our model mainly aims to simulate the lateral transfer of sediment and carbon at
 410 the decadal to centennial timescale, rather than covering the past thousands of years or even
 411 longer time periods, we did not consider the evolution and diversion of river channels in our
 412 study.

413 2.2.2 POC transport and decomposition

414 Many studies described the selective transport of POC and sediment of different particle sizes.
 415 The enrichment ratio (defined as the ratios of fraction of any given component in the transported
 416 sediment to that in the eroded soils) of POC in the transported sediment generally showed
 417 significant positive correlation to the fine sediment particles (e.g. fine silt and clay), but negative
 418 correlation to the coarse sediment particles (Galy et al., 2008; Haregeweyn et al., 2008; Nadeu et
 419 al., 2011; Nie et al., 2015). In ORCHIDEE-C_{lateral}, the physical movements of POC in inland
 420 water systems are simply assumed to follow the flows of finest clay-sediment (Fig. 2b). For
 421 example, the fractions of riverine suspended POC which is deposited on the river bed (F_{rd_POC} , g
 422 C day⁻¹) or is transported to the river channel ($F_{down2riv_POC}$, g C day⁻¹) or floodplain ($F_{riv2fld_POC}$,
 423 g C day⁻¹) are assumed to be equal to the corresponding fractions of clay-sediment (Eqs. 19-21).
 424 Also flows of suspended POC in flooding waters to floodplain soil (F_{fd_POC} , g C day⁻¹) or back to
 425 the stream reservoir ($F_{fld2riv_POC}$, g C day⁻¹), as well as the resuspension of POC from the river
 426 bed (F_{rero_POC} , g C day⁻¹) are scaled to the simulated flows of clay-sediment (Eqs. 22-24). Note
 427 that, similar to SOC, the POC in aquatic reservoirs are divided into three pools: the active
 428 (POC_a), slow (POC_s) and passive pool (POC_p) (Fig. 2a). The eroded active, slow and passive
 429 SOC flow into the corresponding POC pools in the ‘fast’ water reservoir (Fig. 2b).

$$430 \quad F_{rd_POC} = S_{riv_POC} \frac{F_{rd_sed_clay}}{S_{riv_sed_clay}} \quad (19)$$

$$431 \quad F_{down2riv_POC} = S_{riv_POC} \frac{F_{down2riv_sed_clay}}{S_{riv_sed_clay}} \quad (20)$$

$$432 \quad F_{riv2fld_POC} = S_{riv_POC} \frac{F_{riv2fld_sed_clay}}{S_{riv_sed_clay}} \quad (21)$$

$$433 \quad F_{fd_POC} = S_{fld_POC} \frac{F_{fd_sed_clay}}{S_{fld_sed_clay}} \quad (22)$$

$$434 \quad F_{fld2riv_POC} = S_{fld_POC} \frac{F_{fld2riv_sed_clay}}{S_{fld_sed_clay}} \quad (23)$$

$$435 \quad F_{bed2fld_POC} = S_{rivbed_POC} \frac{F_{bed2fld_sed}}{S_{rivbed_sed}} \quad (24)$$

436 The representation of POC deposition and transformation in the aquatic reservoirs and bed
 437 sediment involve as well decomposition, which follows largely the scheme used for SOC (Fig.

438 2a). However, instead of using the rate modifiers for soil temperature and moisture used in the
 439 soil carbon module, daily decomposition rates (F_{POC_i} , g C day⁻¹) of each POC pool (S_{POC_i} , g C)
 440 are simulated to vary with water temperature based on the Arrhenius term which is used to
 441 simulate the DOC decomposition in ORCHILEAK (Hanson et al., 2011; Lauerwald et al., 2017):

$$442 \quad F_{POC_i} = S_{POC_i} \frac{1.073^{(T_{water}-28.0)}}{\tau_{poc_i}} \quad (25)$$

443 where T_{water} (°C) is the temperature of water reservoirs and is calculated from local soil
 444 temperature using an empirical function (Lauerwald et al., 2017). For the POC stored in bed
 445 sediment, temperature of the stream reservoir is used to calculate the decomposition rate. τ_{POC_i} is
 446 the turnover time of the i (active, slow and passive) POC pool. We assumed that the base
 447 turnover times of active (0.3 year) and slow (1.12 years) POC pools are the same as for the
 448 corresponding SOC pools. The passive SOC pool is generally regarded as the SOC which is
 449 associated to soil minerals or enclosed in soil aggregates (Parton et al., 1987). During the soil
 450 erosion and sediment transport processes, the aggregates break down and the passive POC loses
 451 its physical protection from decomposition (Chaplot et al., 2005; Hu and Kuhn, 2016; Polyakov
 452 and Lal, 2008; Wang et al., 2014a). To represent the acceleration of passive POC decomposition
 453 due to aggregate breakdown, we assume that the turnover time of the passive POC is same to the
 454 active POC (0.3 year), rather than the passive SOC (462 years). Similar to the scheme used to
 455 simulate SOC decomposition in ORCHILEAK, the decomposed POC from each of the active,
 456 slow and passive pool flows to other POC pools, to DOC pools or is released to the atmosphere
 457 as CO₂ (Fig. 2). Fractions of the decomposed POC flowing to different POC and DOC pools or
 458 to the atmosphere are set to the same values used in ORCHILEAK for simulating the fates of the
 459 decomposed SOC pools.

460 Changes in the vertical SOC profile of floodplain soils following sediment deposition is
 461 simulated at the end of every daily modelling time-step, after physical transfers and
 462 decomposition of POC have been calculated. The sediment deposited on the floodplain becomes
 463 part of the surface soil layer, and the active, slow and passive POC flow into the active, slow and
 464 passive SOC pools in surface soil layer, respectively. SOC in the original surface and subsurface
 465 soil layers is transferred sequentially to the adjacent deeper soil layers. As the vertical soil profile
 466 in ORCHILEAK is described by an 11-layer discretization of a 2 m soil column, we introduce a

467 deep (> 2 m) soil pool (S_{deep}) to represent the soil and carbon transferred down from the 11th soil
468 layer following ongoing floodplain deposition. Decomposition rates of the organic carbon in this
469 deep soil pool are assumed to be same to those in the 11th (deepest) soil layer. Note that when
470 the soil erosion rate of the floodplain soil is larger than the sediment deposition rate, sediment
471 and organic carbon in S_{deep} move up to replenish the stocks of the 11th soil layer.

472 **2.3 Model application and evaluation**

473 In this study, ORCHIDEE- $C_{lateral}$ was applied over Europe and parts of Middle East ($-30W-70E$,
474 $34N-75N$), where extensive observation datasets are available to calibrate and evaluate our
475 model (Table 1). The return period of daily bankfull flow ($P_{flooding}$, year), which represents the
476 average interval between two flooding events and is used in this study to produce the forcing file
477 of S_{rivmax} from a pre-run of ORCHILEAK. Note that $P_{flooding}$ is generally shorter than the return
478 period of real flooding events, as the flooding may occur in several continuous days and all the
479 flooding waters occurring on these continuous days are generally regarded to belong to the same
480 flooding event (supplementary Fig. S2). To our knowledge, existing observational data on
481 $P_{flooding}$ are still very limited. Therefore, following Schneider *et al.* (2011), we also use a constant
482 $P_{flooding}$ to simulate the bankfull flows from European rivers and the observed long-term (1961–
483 2000) average bank full flow rate ($m^3 s^{-1}$) at 66 sites obtained from Schneider *et al.* (2011) was
484 used to calibrate $P_{flooding}$ (the optimized value is 0.1 year, Table 2). To our knowledge, there is
485 still no large-scale observation data on the sediment delivery rates from land to river networks in
486 Europe to our knowledge. Therefore, following Zhang *et al.* (2020), the parameters a, b, c and d
487 in Eq. 1 and 2 (Table 2) were calibrated at for 57 European catchments (Fig. S3d) against the
488 modelled sediment delivery data obtained from the European Soil Data Centre (ESDAC, Borrelli
489 *et al.*, 2018). The sediment delivery data from the ESDAC product is simulated by the was
490 derived from WaTEM/SEDEM model simulations using high-resolution data of topography, soil
491 erodibility, land cover and rainfall. It has been This model was calibrated and validated using
492 observed sediment fluxes from 24 European catchments (Borrelli *et al.*, 2018).

493 Parameters controlling sediment transport, deposition and re-detachment (i.e. ω , C_{rivdep} , C_{flddep} ,
494 C_{ebed} and C_{ebank} , Table 2) in stream and flooding reservoirs were calibrated against the observed
495 long-term averaged sediment discharge rate (Table 1). We also conducted a sensitivity analysis
496 to test the sensitivity of the simulated riverine sediment and carbon discharges to these

497 parameters, following the method used in Tian et al. (2015). The sensitivity of simulation results
 498 was evaluated based on the relative changes in simulated riverine sediment and carbon
 499 discharges to a 10% increase and decrease of each parameter (Table 2). Result of the sensitivity
 500 analysis shows that the simulated riverine sediment and POC discharges are most sensitive to
 501 c_{rivdep} in Eq. 10, followed by ω in Eq. 8 (Fig. S4). Compared to c_{rivdep} and ω , the simulated
 502 riverine sediment and POC discharges are less sensitive to c_{flddep} , c_{ebed} and c_{ebank} . With 10%
 503 changes in c_{flddep} , c_{ebed} or c_{ebank} , the changes in riverine sediment and POC discharges are
 504 generally less than 3%. In addition, the changes in simulated riverine DOC and CO₂ discharges
 505 are mostly less than 1% with 10% changes in ω , c_{flddep} , c_{ebed} and c_{ebank} . Nonetheless, a 10%
 506 change in c_{rivdep} can lead to a change of about 5% in the simulated riverine CO₂ discharge (Fig.
 507 S4).

508 **Table 2** Values of the key parameters used in the ORCHIDEE-C_{lateral} to simulate the lateral
 509 transfer of sediment and carbon.

Parameter	Value	Unit	Description	Source
a	26.96	Unitless	Coefficient in Eq. 1	Calibrated
b	0.76	Unitless	Coefficient in Eq. 1	Calibrated
c	1.79	Unitless	Coefficient in Eq. 2	Calibrated
d	-0.065	Unitless	Coefficient in Eq. 2	Calibrated
c_{ebed}	0.5	Unitless (0-1)	The fraction of sediment deficit that can be complemented by erosion of river bed (Eq. 6)	Calibrated
c_{ebank}	0.5	Unitless (0-1)	The fraction of sediment deficit that can be complemented by erosion of river bank (Eq. 6)	Calibrated
c_{rivdep}	0.1, 0.2, 0.5 ^a	Unitless (0-1)	Daily deposited fraction of the sediment surplus in stream reservoir (Eq. 5)	Calibrated
c_{flddep}	0.5, 1.0, 1.0 ^a	Unitless (0-1)	Daily deposited fraction of the sediment surplus in flooding reservoir (Eq. 11)	Calibrated
$P_{flooding}$	0.1	year	Return period of daily bankfull flow	Calibrated
τ_{fast}	3.0	day	A factor which translates the topographic index into the water residence time of the 'fast' reservoir (Eqs. 5, 6)	Guimberteau et al., 2012

τ_{flood}	1.4	day	A factor which translates the topographic index into the water residence time of the flooding reservoir (Eq. 18)	Guimberteau et al., 2012
τ_{poc}	0.3, 1.12, 0.3 ^b	year	A factor which translates the topographic index into the water residence time of the flooding reservoir (Eq. 25)	Lauerwald et al., 2017
ω	12.0, 5.0, 2.5 ^a	g s ⁻¹	Coefficient of proportionality for calculating sediment transport capacity (Eq. 8)	Calibrated

510 ^a For clay, silt and sand sediment, respectively. ^b For active, slow and passive POC, respectively.

511

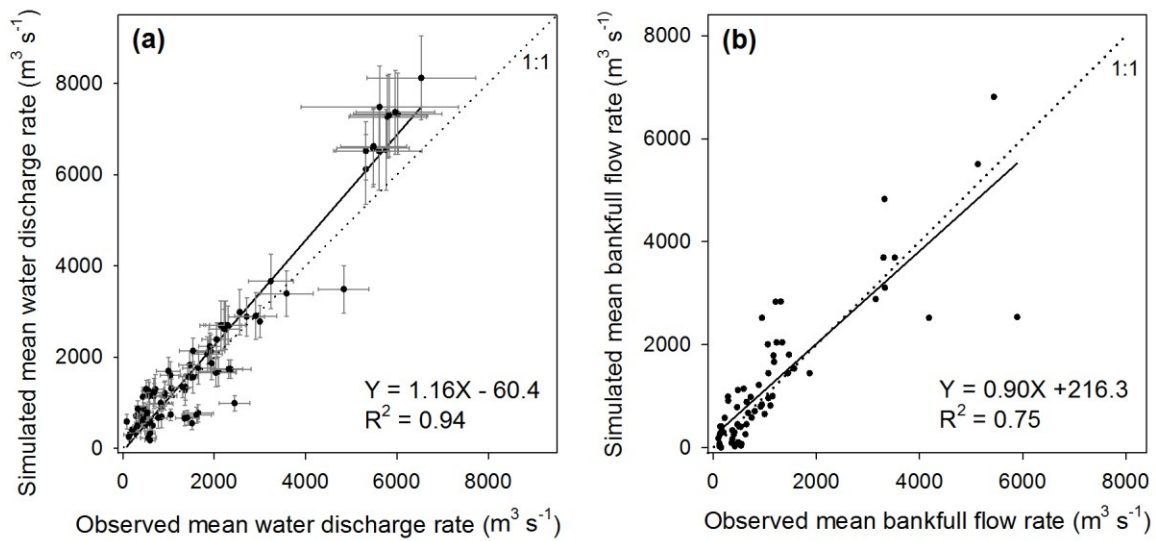

512 After parameter calibration, ORCHIDEE-C_{lateral} was applied to simulate the lateral transfers of
513 water, sediment and organic carbon in European rivers over the period 1901-2014. Before this
514 historical simulation, ORCHIDEE-C_{lateral} was run over 10,000 years (spin-up) until the soil
515 carbon pools reached a steady state. In the ‘spin-up’ simulation, the PFT maps, atmospheric CO₂
516 concentrations and meteorological data during 1901–1910 were used repeatedly as forcing data.
517 The finally simulated water discharge rates in European rivers were evaluated using observation
518 data at 93 gauging sites (locations see Fig. S3a) from the Global Runoff Data Base (GRDC,
519 Table 1). The simulated bankfull flows were evaluated against observed long-term (1961–2000)
520 average bankfull flows at 66 sites (Fig. S3b) from Schneider *et al.* (2011). The simulated riverine
521 sediment discharge rate is evaluated using observation data from the European Environment
522 Agency and existing publications (see Table 1) at 221 gauging sites (Fig. S3c). The riverine total
523 organic carbon (TOC), POC and DOC concentrations provided by the GLObal RIver Chemistry
524 Database (GLORICH, Hartmann et al., 2019) at 346 sites (Fig. S3d) were used to evaluate the
525 simulated riverine POC and DOC concentrations. Note that observations in the GLORICH
526 database which are measured at gauging sites with drainage area <1.0×10⁴ km² were excluded
527 from our model evaluation, because these small catchments cannot be represented by the coarse
528 river network scheme at 0.5 degree (ca. 55 km at the equator). Among the retained 346 gauging
529 sites, TOC concentrations were measured at 188 sites, DOC was measured at 314 sites. POC was
530 measured at only two sites (Bad honnef (51 measurements) and Bimmen (78 measurements)) in
531 the Rhine catchment and one site (Rheine, 36 measurements) in the Ems catchment (Fig. S3d).

532 **3 Results and Discussion**

533 **3.1 Model evaluation**

534 3.1.1 Stream water discharge and bankfull flow

535 Evaluation of our simulation results using *in situ* observation data from Europe rivers indicates
536 that ORCHIDEE-C_{lateral} well reproduces the magnitude and interannual variation of water
537 discharge rates in major European rivers (Figs. 3a and S5). Overall, the simulated riverine water
538 discharge rate explained 94% (Fig. 3a) of the spatial variation of the observed long-term average
539 water discharge rates across 93 gauging sites in Europe (Fig. S3a). Relative biases (calculated as:
540 $\frac{\text{simulation} - \text{observation}}{\text{observation}} \times 100\%$, as used through the manuscript if not otherwise stated) of the
541 simulated average water discharge rates compared to the observations are mostly smaller than
542 30% (Fig. 3a). For major European rivers, such as the Rhine, Danube, Elbe, Rhone and Volga,
543 ORCHIDEE-C_{lateral} also captures the interannual variation of the water discharge rate (Fig. S5).
544 We recognize that ORCHIDEE-C_{lateral} may overestimate or underestimate the water discharge
545 rate in some rivers (Fig. 3a), particularly in smaller rivers where discrepancy between the stream
546 routing scheme (delineation of catchment boundaries) extracted from the forcing data at 0.5°
547 resolution and the real river network (Fig. S6) can be substantial. An over-estimation or
548 underestimation of the catchment area by the forcing data as respectively found for the Elbe and
549 Rhine will introduce a proportional bias in the average amount of simulated discharge from these
550 catchments. Another problem are stream channel bifurcations which occur in reality, but which
551 are not represented in a stream network derived from a digital elevation model. For example, in
552 the Danube river delta, a fraction of the discharge is actually exported to the sea through the
553 Saint George Branch, in addition to the water discharge through the main river channel (Fig.
554 S6b). This explains why the simulated water discharge rate at the outlet of the Danube catchment
555 is larger than the observation at the Ceatal gauging station, Romania (identify number in the
556 GRDC database is 6742900, Fig. S5m), where only the main stream discharge was measured.

557

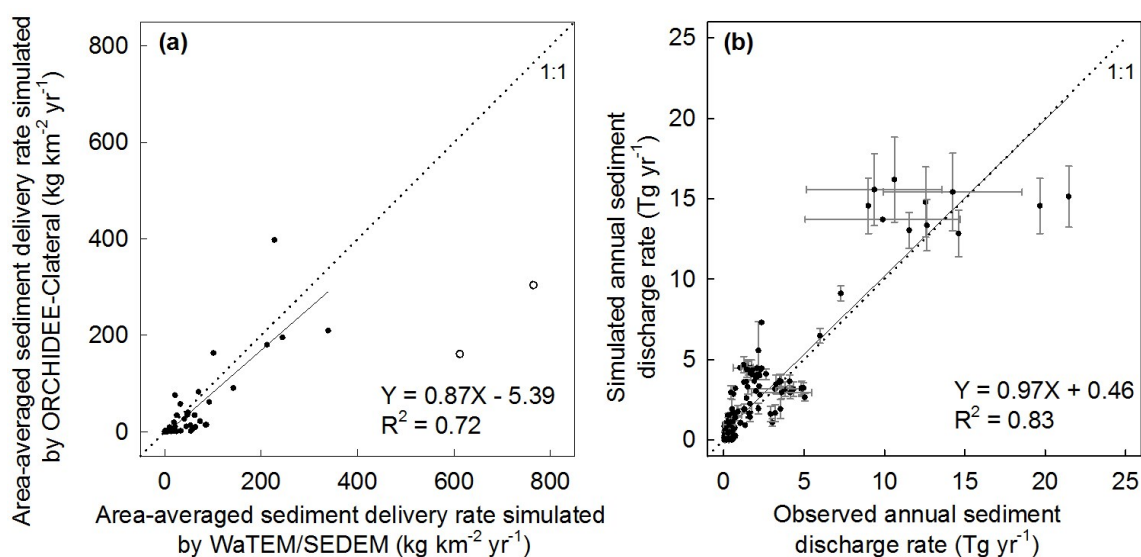

558 **Figure 3** Comparison between observed and simulated riverine water discharge rates (a) and
 559 bankfull flow rates (b). In figure (a), the error bar denotes the standard deviation of interannual
 560 variation. Sources of the observed riverine water discharge rate and bankfull flow rate can be
 561 found in Table 1.

562 With the calibrated return period (= 0.1 year) of the daily flooding rate (see section 2.3), the
 563 simulated bankfull flow rates compare well to observations at the 66 sites for which data was
 564 available (Fig. 3b). Overall, the simulation result explained 75% of the inter-site variation of the
 565 observed bankfull flow rates. Relative biases of the simulated bankfull flow rates are generally
 566 lower than 30%, although the relative bias may be larger than 100% at some sites.

567 3.1.2 Sediment transport

568 The simulated area-averaged sediment delivery rates from upland to river network by the
 569 ORCHIDEE-C_{lateral} are overall comparable to those simulated by the WaTEM/SEDEM for most
 570 catchments in Europe (Figs. 4a and S3d). In the two catchments in the Apennine Peninsula,
 571 ORCHIDEE-C_{lateral} gives a drastically lower estimation on the sediment delivery rates compared
 572 to WaTEM/SEDEM. By excluding these two catchments, ORCHIDEE-C_{lateral} reproduces 72% of
 573 the spatial variation of the sediment delivery rates estimated by the WaTEM/SEDEM (Fig. 4a).
 574 In addition, the average sediment loss rate over all catchments showed in Fig. S3d is 40.8 g m⁻²
 575 yr⁻¹, which is overall comparable to the estimate by the WaTEM/SEDEM (42.5 g m⁻² yr⁻¹).

576 ORCHIDEE-C_{lateral} reproduces 83% of the inter-site variation of the observed riverine sediment
 577 discharge rates across Europe (Fig. 4b). Simulation of the riverine sediment discharge rate at
 578 large spatial scale is still a big challenge. It generally needs detailed information on the stream
 579 flow, geomorphic properties of river channel and the particle composition of the suspended
 580 sediment (Neitsch et al., 2011). Moreover, the parameters of existing sediment transport models
 581 usually require recalibration when they are applied to different catchments (Gassman et al.,
 582 2014; Oeurng et al., 2011; Vigiak et al., 2017). In ORCHIDEE-C_{lateral}, the sediment processes in
 583 river networks are simulated using simple empirical functions and parameters based on a routing
 584 scheme at a spatial resolution of 0.5° (section 2.2.1). Detailed information about the stream flow
 585 (e.g. cross-sectional area) and the geomorphic properties of river channels are not represented.
 586 Sediment discharge in all catchments was simulated using a universal parameter set. This may
 587 explain why ORCHIDEE-C_{lateral} fails to capture the observed sediment discharge rates in some
 588 specific catchments, especially those with relatively small drainage areas (e.g. $< 5 \times 10^3$ km²).

589
 590 **Figure 4** Comparison between the simulated area-averaged sediment delivery rate from uplands
 591 to river network from ORCHIDEE-C_{lateral} and WaTEM/SEDEM (a), and the comparison between
 592 observed and simulated annual sediment discharge rates at 221 gauging sites (b). In figure (a),
 593 the two hollow dots represent the sediment delivery rates at the two catchments in the Apennine
 594 Peninsula (Fig. S3d). The regression function in figure (a) was obtained based on the values of
 595 all solid dots, excluding the two hollow dots. In figure (b), the error bar denotes the standard

596 deviation of interannual variation. Sources of the observed annual sediment discharge rate in
597 Table 1.

598 **3.1.3 Organic carbon transport**

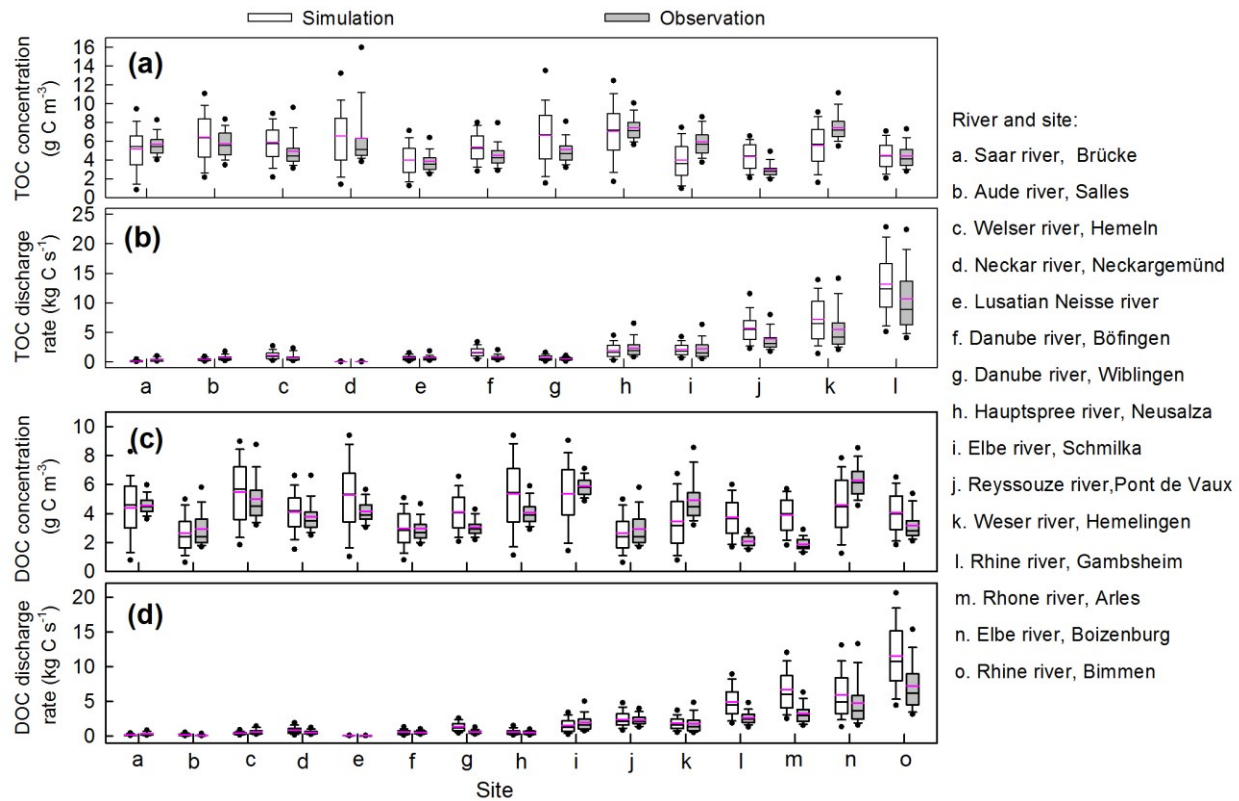

599 Simulation of the riverine carbon discharge rate at large spatial scale is even a bigger challenge
600 than simulating sediment discharge, as the riverine carbon discharge is controlled by many
601 factors, such as upland topsoil SOC concentrations, soil erosion rate, transport and deposition
602 rate of clay fraction in river channel and on floodplain, and the decomposition of POC in transit
603 and in aquatic sediments. As described above, the simulated water discharge rate, bankfull flow
604 and sediment discharge rate are overall comparable to observation (Figs. 3 and 4). The simulated
605 total SOC stock in the top 0-30 cm soil layer in Europe of 107 Pg C is close to the value
606 extracted from the HWSD database (106 Pg C), but significantly lower than the values extracted
607 from some other databases, such as the GSDE (249 Pg C), SoilGrids (202 Pg C), S2017 (148 Pg
608 C) and landGIS (226 Pg C) (Fig. S7a). We noticed that the SOC stocks extracted from these
609 observation-based soil databases show considerable difference (vary from 106 to 249 Pg C), as
610 they have been produced using different clusters of site-level SOC measurements and different
611 interpolation methods to produce global gridded SOC stocks from the site-level measurements
612 (Shangguan et al., 2014; Hengl et al., 2014; Sanderman et al., 2017). Distribution of the
613 simulated SOC stock along the latitude gradients (30° N – 75° N) are overall comparable to
614 those extracted from the HWSD and S2017 databases (Fig. S7). But even compared to these two
615 databases, our model still underestimated the SOC stock in southern Europe (30° N – 41° N).

616 Comparison of the simulated concentrations of riverine organic carbon and the observations
617 obtained from the GLORICH database (Hartmann et al., 2019) indicates that our model can
618 basically capture the TOC and DOC concentrations in European rivers (Figs 5, 6, S8 and S9).
619 The simulation results explain 34% and 32% of the inter-site variation of the observed TOC and
620 DOC concentrations, respectively (Fig. 5). For major European rivers, such as the Rhine, Elbe,
621 Danube, Spree and Weser, the simulated long-term average TOC and DOC concentrations are
622 overall close to the observations (Figs. 6, S8 and S9). But for the Rhone river in southern France,
623 the DOC concentrations have been systematically overestimated by more than 50% (Figs. 6 and
624 S9m). In addition, both simulated and observed TOC and DOC concentrations show drastic
625 temporal (both seasonal and interannual) variations (Figs 5, S8 and S9). Our model seems to

626 have overestimated the temporal variation of TOC and especially DOC concentrations (Figs. S8
627 and S9). Nonetheless, the simulated temporal variation of TOC and DOC discharge rates are
628 overall comparable to the observation (Figs. S10 and S11), as our model can well capture the
629 magnitude and temporal variation of riverine water discharge rates.

630
631 **Figure 5** Comparison between the observed and simulated riverine TOC (a, POC+DOC) and
632 DOC (b) concentrations. The dot and error bar denote the mean and standard deviation at each
633 gauging site, respectively. Note that the mean and standard deviation of the simulated
634 concentrations at each site are calculated based on the monthly average value, but the mean and
635 standard deviation of the observed concentrations are based on instantaneous observation.

636

637 **Figure 6** Comparison between the observed and simulated concentrations of total organic carbon
 638 (TOC, a) and dissolved organic carbon (DOC, b) in river flows, as well as the discharge rates of
 639 riverine TOC and DOC. The black and pink lines in each box denote the median and mean value,
 640 respectively. Box boundaries show the 25th and 75th percentiles, whiskers denote the 10th and 90th
 641 percentiles, the dots below and above each box denote the 5th and 95th percentiles, respectively.

642 In Europe, the GLORICH database only provides POC concentrations measured at three gauging
 643 stations in northwestern Germany (Figs. 7, S3d). The simulated POC concentrations and
 644 discharge rates in the Ems river at Rheine are overall comparable to the observation (Figs. 7e,f).
 645 However, at the two gauging sites at the river Rhine, the POC concentrations have been
 646 significantly underestimated (Figs. 7a-d). We noticed that the stream routing scheme of Rhine
 647 catchment at 0.5° obtained from the forcing data STN-30p (Vörösmarty et al., 2000) differs
 648 significantly from the stream routing scheme extracted based on high resolution (3") DEM (Fig.
 649 S6). Thus, besides the errors in simulated SOC stocks, soil erosion rate, stream discharge rate,
 650 and sediment transport and deposition rate, the inaccurate stream routing scheme used in this
 651 study might also be an important reason for the underestimation of POC concentration in Rhine
 652 river.

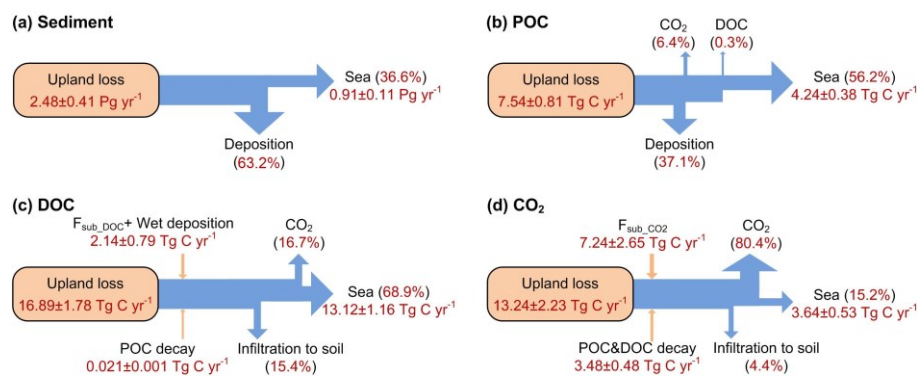

653

654 **Figure 7** Comparison between observed (instantaneous measurements) and simulated (monthly
 655 average values) riverine POC concentrations and POC discharge rates at three gauging sites. The
 656 histograms and error bars denote the means and standard deviations of POC concentrations,
 657 respectively. Long-term average water discharge rates at Bad Honnef, Bimmen and Rheine
 658 during the observation periods are 2023, 2100 and 80 m³ s⁻¹, respectively.

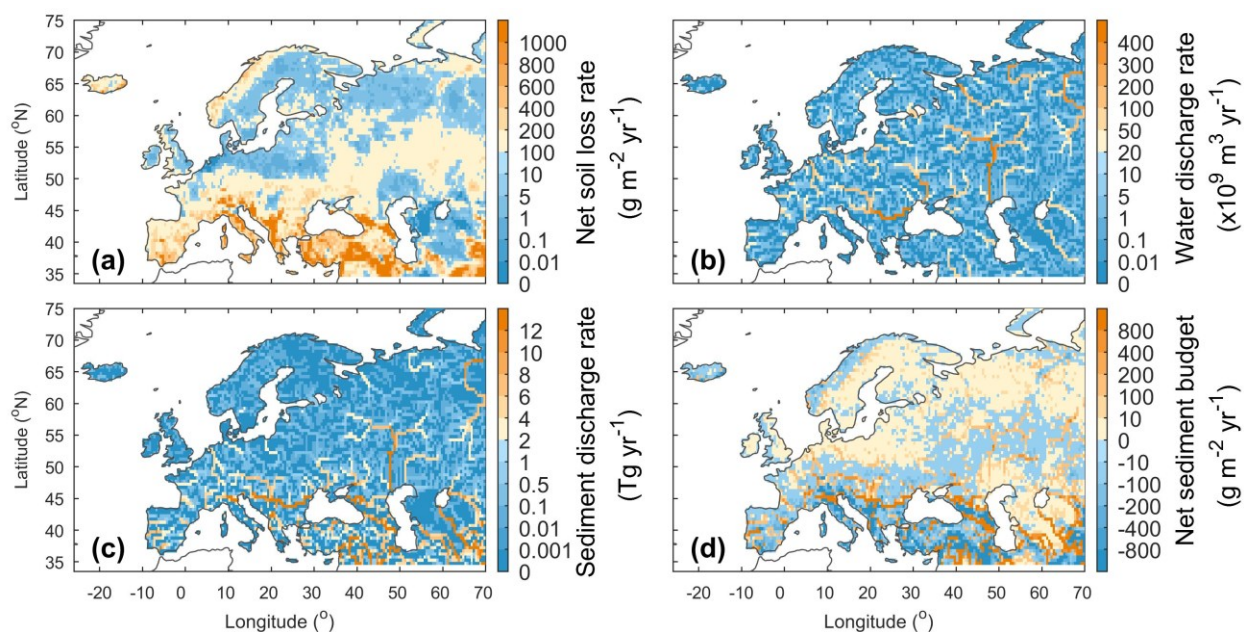

659 3.2 Lateral carbon transfers in Europe

660 Based on our simulation results, the average annual sediment delivery from upland to the river
 661 network caused by water erosion in Europe (-30W– 70E, 34N-75N) during 1901-2014 is 2.8±0.4
 662 Pg yr⁻¹ (Fig. 8a). From Northern to Southern Europe, the sediment delivery rate from upland to
 663 river increase from less than 1.0 g m⁻² yr⁻¹ in the Scandinavia Peninsula, which is covered by
 664 mature boreal forests (Fig. S12a), and in the Northern European Plain to more than 600 g m⁻² yr⁻¹
 665 in the mountainous regions of the Apennine Peninsula, Balkan Peninsula and the Middle East
 666 (Figs. 9a, S13a). In total across Europe, 63.2% (1.8±0.2 Pg yr⁻¹) of the sediment delivered into
 667 river network is deposited in river channels and floodplains, and the remaining 36.8% (1.0±0.1
 668 Pg yr⁻¹) is exported to the sea (Fig. 8a). Generally, large rivers, like Danube, Volga, and Ob
 669 rivers, carry more sediment to the sea than small rivers (Figs. 9b, c). But several relatively small

670 rivers in the Middle East and the Po river in northern Italy also carry similarly large amount of
 671 sediment to the sea, as the upland soil erosion rates are very high ($> 200 \text{ g m}^{-2} \text{ yr}^{-1}$) in these
 672 catchments (Figs. 9a, c). Spatial distribution of the sediment deposition is controlled by the
 673 stream routing scheme and the spatial distribution of floodplains (Fig. 10b). In Northern and
 674 Central Europe, the area-averaged sediment deposition rates (i.e. amount of annual sediment
 675 deposition /area of $0.5^\circ \times 0.5^\circ$ grid cell) in river channels and floodplains are mostly less than
 676 $100.0 \text{ g m}^{-2} \text{ yr}^{-1}$ (Fig. 9d). In the downstream part of the Danube, Po and several rivers in the
 677 Middle East, the sediment deposition rate can exceed $800.0 \text{ g m}^{-2} \text{ yr}^{-1}$. From 1901 to 1960s, the
 678 annual total sediment delivery from uplands to the whole river network of Europe declined
 679 significantly ($p < 0.01$, independent sample t-test) from about 3.0 Pg yr^{-1} to about 2.3 Pg yr^{-1} (Fig.
 680 S14a). From 1960 to 2014, the annual sediment delivery rate did not show a significant trend, but
 681 revealed large interannual variations.

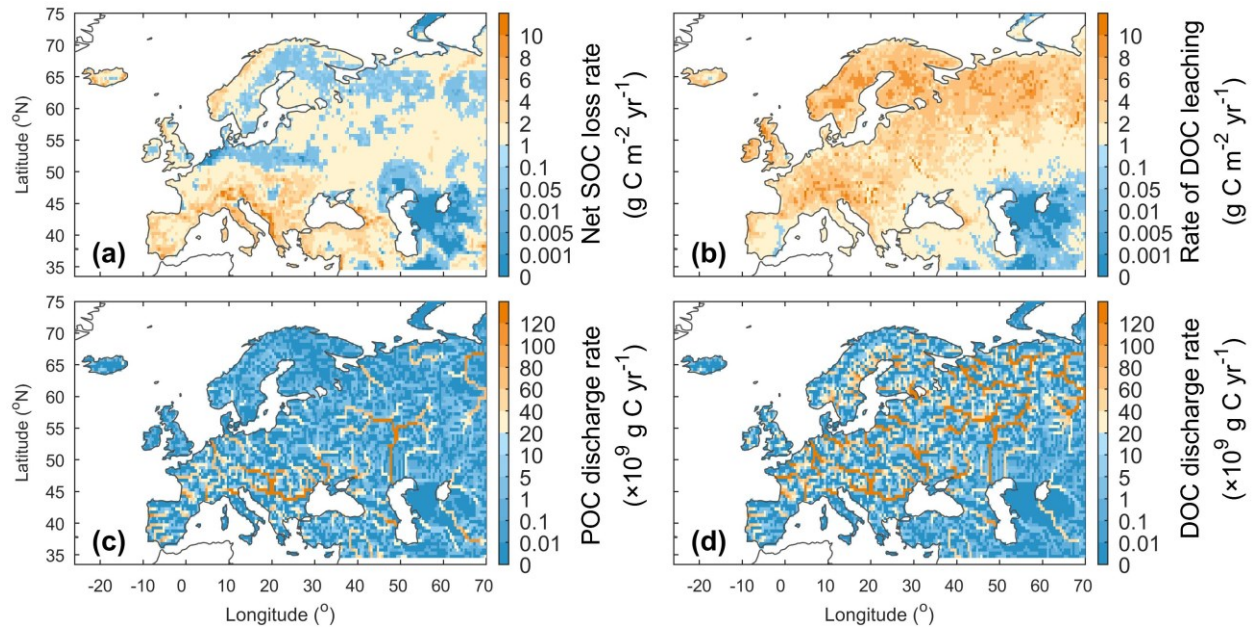

682
 683 **Figure 8** Averaged annual lateral redistribution rate of sediment (a), POC (b), DOC (c) and CO_2
 684 (d) in Europe for the period 1901-2014. $F_{\text{sub_DOC}}$ and $F_{\text{sub_CO}_2}$ are the DOC and CO_2 inputs from
 685 floodplain soil (originated from the decomposition of submerged litter and soil carbon) to the
 686 overlying flooding water, respectively.

687

688 **Figure 9** Averaged annual lateral redistribution rate of water and sediment in Europe during
 689 1901-2014. (a) Annual sediment delivery rate from upland to river network; (b) annual water
 690 discharge rate; (c) annual sediment discharge rate and (d) annual net sediment budget in each
 691 $0.5^\circ \times 0.5^\circ$ grid cell. In figure d, the positive and negative values denote net gain and net loss of
 692 sediment, respectively.

693 Along with soil erosion and sediment transport, the average annual POC delivery from upland to
 694 river network in the whole Europe during 1901-2014 is 10.1 ± 1.1 Tg C yr⁻¹ (Fig. 8b). 41.0% of
 695 the POC delivered into the river network is deposited in river channels and floodplains, 2.9% is
 696 decomposed during transport, and the remaining 56.1% is exported to the sea. Spatial patterns of
 697 the area-averaged SOC delivery rate and POC discharge rate basically follow that of sediment
 698 (Fig. 10a, c). Although the sediment discharge rates in some rivers in the Middle East can be as
 699 high as that in the Danube or Volga river (Fig. 9c), the POC delivery rates in these rivers are
 700 much smaller than in the larger ones (Fig. 10c). This is mainly due to the lower SOC stocks in
 701 the Middle East compared to those found in the Danube and Volga catchments (Fig. S7). We
 702 also note that different from the sediment delivery, the annual total POC delivery from upland to
 703 river network in Europe did not show a significant declining trend from 1901 to 1960s (Fig.
 704 S14b). The increase in SOC stock (Fig. S14c) may have partially offset the decline in sediment
 705 delivery rate.

706

707 **Figure 10** Averaged annual lateral redistribution rate of organic carbon in Europe during 1901-
 708 2014. (a) Annual SOC delivery rate from upland to river network; (b) annual DOC leaching rate;
 709 (c) annual POC discharge rate and (d) annual DOC discharge rate.

710 Leaching results in an average annual DOC input of $13.5 \pm 1.5 \text{ Tg C yr}^{-1}$ from soil to the river
 711 network in Europe, and the *in-situ* DOC production caused by wet deposition and the
 712 decomposition of riverine POC and submerged litter and soil organic carbon under flooding
 713 waters amounts to $2.2 \pm 0.7 \text{ Tg C yr}^{-1}$ (Fig. 8c). 28.1% of the total riverine DOC is then infiltrating
 714 into the floodplain soils, 12.9% is decomposed during riverine transport, and the remaining
 715 59.0% is exported to the sea. The spatial distribution of the DOC leaching rate is very different
 716 from that of POC (Fig. 10b). From North-western Europe to Southeast Europe and the Middle
 717 East, the DOC leaching rates decrease from over $6 \text{ g C m}^{-2} \text{ yr}^{-1}$ to less than $1.0 \text{ g C m}^{-2} \text{ yr}^{-1}$. DOC
 718 discharge rates in major European rivers, such as Rhine, Danube, Volga, Elbe and Ob, are mostly
 719 higher than 100 Tg C yr^{-1} (Fig. 10d). Comparatively, the DOC discharge rates in Southern
 720 Europe and the Middle East are significantly lower ($< 60 \text{ Tg C yr}^{-1}$).

721 The average annual leaching rate of CO_2 sourced from the decomposition of upland litter and
 722 soil organic carbon (incl. DOC) in the whole Europe is $14.3 \pm 2.2 \text{ Tg C yr}^{-1}$ (Fig. 8a).

723 Decomposition of the submerged litter and organic carbon in floodplains and the decomposition
 724 of riverine POC and DOC add an *in-situ* CO_2 production amounting to $7.5 \pm 2.7 \text{ Tg C yr}^{-1}$ and

725 4.1±0.5 Tg C yr⁻¹, respectively. Most of this CO₂ (80.2%) feeding stream waters is then released
 726 back to the atmosphere quickly, in such a way that only 15.8% of the CO₂ is exported to the sea,
 727 and 4.0% is infiltrated into the floodplain soils.

728 3.3 Implications for the terrestrial C budget of Europe

729 Representing the lateral carbon transport in LSM is helpful to estimate the terrestrial carbon
 730 cycle more accurately. From the year 1901 to 2014, soil erosion and leaching combined resulted
 731 in a 5.4 Pg loss of terrestrial carbon to the European river network, this amount corresponding to
 732 about 5% of the total SOC stock (106 Pg C, Fig. S7a) in the 0-30 cm soil layer. The average
 733 annual total delivery of organic carbon (POC+DOC) during the same period is 47.3±6.6 Tg C yr⁻¹
 734 (Fig. 8), which is about 4.7% of the net ecosystem production (NEP (993±255 Tg C yr⁻¹),
 735 defined as the difference between the vegetation primary production (NPP) and the soil
 736 heterotrophic respiration (Rh) due to the decomposition of litter and soil organic matter, i.e.
 737 NEP=NPP–Rh), and 19.2% of the net biome production (NBP (243±189 Tg C yr⁻¹), defined as
 738 the difference between NEP and the land carbon loss (Rd) due to the additional disturbances (e.g.
 739 harvest, land cover change, and soil erosion and leaching, i.e. NBP=NEP–Rd–DOC and POC to
 740 river) (Fig. 11b). The annual total export of carbon to the sea surrounding Europe is 19.0±1.4 Tg
 741 C yr⁻¹, which amounts to 1.9% and 8.7% of the NEE and NBP, respectively.

742 (a) No lateral C transport (b) With lateral C transport

743 **Figure 11** The simulated average annual carbon budget of the terrestrial ecosystem in Europe
 744 during the 1901-2014 when the lateral carbon transport is ignored (a) and considered (b). All
 745 fluxes are presented as mean ± standard deviation. NPP is the net primary production. Rh and Rd
 746 are the heterotrophic respiration and the respiration due to disturbances like harvest and land
 747 cover change, respectively. ΔC_{land} is the average annual changes of the total land carbon stock.
 748 Percentage following each of these changes in blue is the average annual relative changes of the
 749 corresponding carbon pool. C_{land2riv}, C_{riv2land} and C_{riv2sea} are the average annual carbon fluxes

750 from land to inland waters, from inland waters to floodplains and from inland waters to the sea,
751 respectively. SD is the standard deviation.

752 Besides direct transfers of organic carbon from soil to aquatic systems, the lateral transport of
753 water, sediment and carbon can also affect the land carbon budget through several indirect ways.
754 First, the lateral redistribution of surface runoff can affect the land carbon budget by altering soil
755 wetness. Our simulation results reveal that the lateral redistribution of runoff can significantly
756 change local soil wetness, especially in floodplains (Fig. S13b), where the increase in soil
757 wetness can be larger than 10% (Fig. S16b). Soil wetness is a key controlling factor of plant
758 photosynthesis (Knapp et al., 2001; Stocker et al., 2019; Xu et al., 2013). Benefiting from the
759 increase in soil wetness, the NPP in many grid cells with a large area of floodplain has increased
760 by more than 5% (Fig. 11b), although the NPP over the whole Europe only increased by 1%
761 (Fig. 11). Changes in soil wetness can further alter soil temperature (Fig. S16a). As soil wetness
762 and temperature are the two most important controlling factors of organic matter decomposition,
763 the lateral redistribution of runoff can affect local land carbon budget by changing the Rh.
764 Moreover, in ORCHIDEE-C_{lateral}, the turnover times of litter and SOC under flooding waters
765 (assumed to experience anaerobic condition) are set to be one third of the litter and SOC turnover
766 times in upland soil (Reddy & Patrick Jr, 1975; Neckles & Neill, 1994; Lauerwald et al., 2017).
767 Accounting for flooding thus decreases the decomposition rate of litter and SOC stored in
768 floodplain soils.

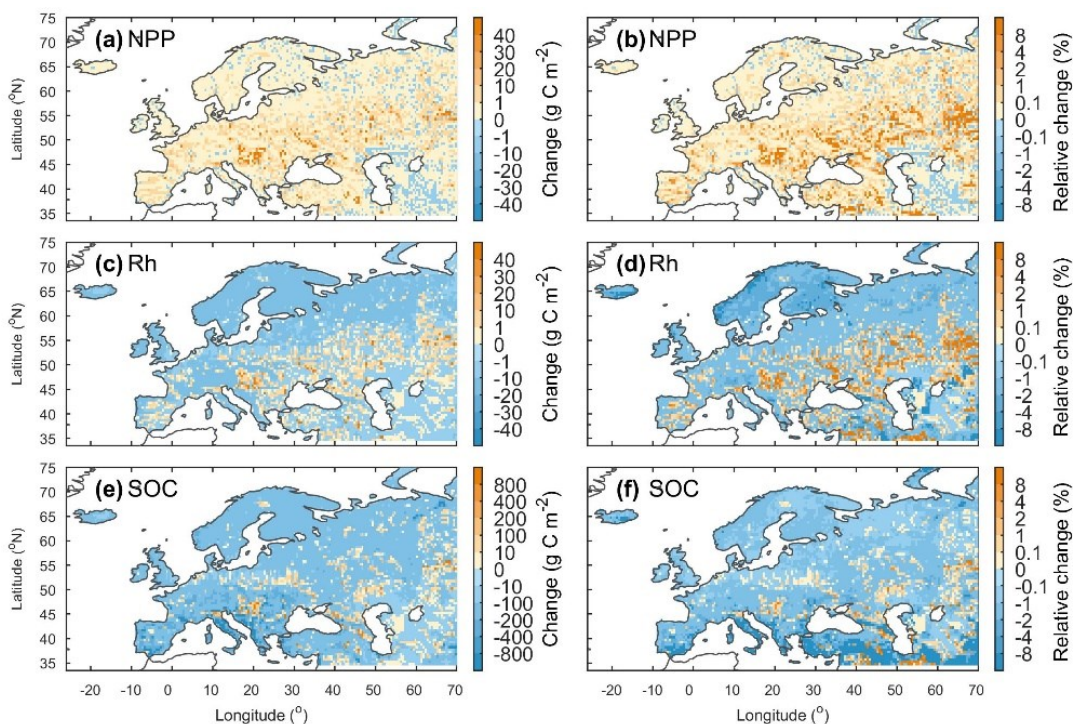

769 Second, soil erosion and sediment deposition can affect land carbon budget by altering the
770 vertical distribution of litter and soil organic carbon. At the net erosion sites of the uplands, the
771 loss of surface soil results in a part of the belowground litter and SOC that were originally stored
772 in deeper soil layers emerging to the surface soil layers, and also results in a fraction of the
773 belowground litter becoming the aboveground litter. In the floodplains, the newly deposited
774 sediment becomes part of the surface soil layer, and the belowground litter and SOC in the
775 original surface soil layer is transferred down to the deeper soil layers. As the temperatures and
776 fresh organic matter inputs (sourced from the aboveground litterfall and dead roots), which can
777 impact SOC decomposition rates through the priming effect (Guenet et al., 2016; Guenet et al.,
778 2010), in different soil layers are different, changes in the vertical distribution of belowground

779 litter and SOC can therefore lead to changes in the overall decomposition rate of the organic
780 matter in the whole soil column.

781 Third, soil aggregates mostly break down during soil erosion and sediment transport, the riverine
782 POC thus loses part of its physical protection from decomposition (Hu and Kuhn, 2016; Lal,
783 2003). Some modelling studies have assumed that at least 20% of the eroded SOC would be
784 decomposed during the soil erosion and transport processes (Lal, 2003, 2004; Zhang et al.,
785 2014). However, the estimation by Smith et al. (2001) using a conceptual mass balance model
786 suggest that only a tiny fraction of the eroded POC is decomposed and released as CO₂ to the
787 atmosphere. Using laboratory rainfall-simulation experiments, van Hemelryck et al. (2010)
788 estimated a 2%-12% mineralization of the eroded SOC from a loess soil, and Wang et al. (2014)
789 estimated a mineralization of only 1.5%. In ORCHIDEE-C_{lateral}, the passive SOC pool is
790 regarded as the SOC associated to soil minerals and protected by soil aggregates. The turnover
791 time of the passive POC in river stream and flooding waters is assumed to be same to that of the
792 active POC (0.3 year). Our simulation results suggest that the fraction of total riverine POC that
793 is decomposed during the lateral transport from uplands to the sea is 2.9% in Europe (Fig. 8b),
794 which is larger than the POC decomposition fraction (0.9%) when the turnover time of the
795 passive POC in rivers is assumed to be same to that of the passive POC (i.e. no soil aggregates
796 break down). The acceleration of POC decomposition rate due to the breakdown of soil
797 aggregates can thus slightly affect the estimate of the regional land-atmosphere carbon flux.
798 Moreover, the riverine POC and DOC can be transported over a long distance and finally settle
799 or infiltrate in floodplains or river channels (especially the Estuarine deltas) where the local
800 environmental conditions might be quite different from those encountered in the uplands from
801 where these C pools originate. These changes in environmental conditions can affect the
802 decomposition rate of the laterally redistributed organic carbon (Abril et al., 2002).

803 Comparison between the simulation results from ORCHIDEE-C_{lateral} with activated and
804 deactivated erosion and river routing modules indicate that ignoring lateral carbon transport
805 processes in LSM may lead to significant biases in the simulated land carbon budget (Figs. 11
806 and S14). Although the omission of lateral carbon transport in ORCHIDEE-C_{lateral} only resulted
807 in a 1% decrease in simulated average annual total NPP in Europe during 1901-2014 and a 1%
808 increase of annual total Rh, the annual total NBP (=NEP-Rd-DOC and POC to river) is

809 overestimated by 4.5%. Over the same period, the lateral carbon transport only induced a 0.09%
 810 decrease in the total SOC and DOC stock in Europe (Fig. S15c), but their spatial distribution was
 811 significantly altered (Figs. 12e,f). For instance, in some mountainous regions, the soil erosion
 812 induced a reduction of the SOC stock by more than 8%. On the contrary, the sediment and POC
 813 deposition in some floodplains led to an increase in SOC stock by more than 8% (Fig. 12f).

814
 815 **Figure 12** Changes (first column) and relative changes (second column) of the net primary
 816 production (NPP), heterotrophic respiration (Rh) and total soil organic carbon (SOC, 0-2 m) in
 817 Europe due to the lateral carbon transport during 1901-2014. For each variable, the change is
 818 calculated as $C_{\text{lat}} - C_{\text{no lat}}$, where C_{lat} and $C_{\text{no lat}}$ are the carbon fluxes or stocks when lateral carbon
 819 transport is considered and ignored, respectively. The relative changes is calculated as $(C_{\text{lat}} -$
 820 $C_{\text{no lat}}) / C_{\text{no lat}} \times 100\%$.

821 Consistent with previous studies (Stallard, 1998; Smith et al., 2001; Hoffmann et al., 2013), our
 822 simulation results reveal the importance of sediment deposition in floodplains for the overall
 823 SOC budget. From 1901 to 2014, erosion and leaching over Europe totally induced a loss of 3.03
 824 Pg organic carbon (POC+DOC) from uplands to the river network, and only 0.65 Pg of this
 825 carbon was redeposited onto the floodplains. The total stock of soil organic carbon in Europe
 826 thus should have decreased by 2.38 Pg C. However, due to the decrease in decomposition rate of

827 the buried organic carbon (including in-situ and ex-situ carbon) in floodplain soils, the total stock
828 of soil organic carbon in Europe only decreased by 0.91 Pg C. Floodplains in Europe have totally
829 protected 2.12 (= 3.03 - 0.91) Pg soil organic carbon from been transported to the sea or be
830 released to the atmosphere in forms of CO₂. Although the sequestration of organic carbon in
831 floodplains cannot make up all of the soil organic carbon (POC+DOC) loss, the increased
832 organic carbon stock in floodplains (2.12 Pg C) is much higher than the soil POC loss (0.86 Pg
833 C) induced by soil erosion.

834 **3.4 Uncertainties and future work**

835 In the present version of ORCHIDEE-C_{lateral}, the lateral transfers of sediment and carbon is
836 simulated using a simplified scheme, due to the fragmented nature of large-scale forcing (e.g.
837 geomorphic properties of the river channel) and validation data (e.g. continuous sediment and
838 carbon concentration data in river streams and deposition/erosion rates in river channels). We
839 recognize that this simplification induces significant uncertainties in model outputs, especially
840 regarding changes in lateral sediment and particulate carbon transfers under climate change and
841 direct human perturbations. Several physics-based algorithms have been proposed to accurately
842 calculate the *TC* of stream flows (Arnold et al., 1995; Molinas and Wu, 2001; Nearing et al.,
843 1989). These algorithms mostly require detailed information about the stream power (e.g. flow
844 speed and depth), geomorphic properties of the river channel (e.g. slope and hydraulic radius)
845 and the physical properties of the sediment particles (e.g. median grain size) (Neitsch et al.,
846 2011). They are good predictors to estimate *TC* in rivers with detailed observation data on local
847 stream, soil, geomorphic properties. Unfortunately, it is not practical to implement those
848 algorithms in ORCHIDEE-C_{lateral} due to the lack of appropriate forcing data at large scale as well
849 as the relatively rough representation of stream flow dynamics compared to hydrological models
850 for small basins. For example, runoff and sediment from all headwater basins in one 0.5° grid
851 cell of ORCHIDEE-C_{lateral} are assumed to flow into one single virtual river channel. Although
852 the total river surface area in each grid cell is represented (obtained from forcing file (Table 1),
853 Lauerwald et al., 2015), the length, width and depth of the river channel are unknown.
854 Furthermore, in reality, there can be multiple river channels in the area represented by each grid
855 cell, and these channels might flow to different directions.

856 We also noticed that previous studies have derived empirical functions of upstream drainage area
857 (e.g. Luo et al., 2017) or upstream runoff (e.g. Yamazaki et al., 2011) to calculate the river width
858 and depth, allowing to simulate the water flow in the river channel using physically-based
859 algorithms. Unfortunately, to obtain a good fit of the simulated river discharges against
860 observations, the parameters in the empirical functions for calculating river width and depth
861 generally need to be calibrated separately for each catchment (Luo et al., 2017), an approach that
862 is incompatible with large-scale simulations like those performed here. Without such calibration,
863 the simulated geometrical properties of the river channel and runoff are prone to large
864 uncertainties, thus rendering the simulation of sediment transport at continental or global scale
865 using physically-based algorithms a more challenging task. Given the difficulty to simulate the
866 detailed hydraulic dynamics of the stream flow at large spatial scale, we thus apply a simple
867 approach (Eq. 8) to calculate the sediment transport capacity. Overall, we encourage future
868 studies to produce large-scale databases on the geomorphic properties of global river channels
869 (e.g. river depth and width) and to develop large-scale sediment transport models which can give
870 a capable of producing more realistic and accurate simulations of sediment deposition, re-
871 detachment and transport processes, as well as including the exchanges of water, sediment and
872 carbon between river stream and floodplains.

873 The simulation of the soil DOC dynamics and leaching in our model need to be further improved
874 to better simulate the seasonal variation of riverine DOC and TOC concentrations. The
875 concentration of soil DOC and the DOC decomposition rate during the lateral transport process
876 in the river network are the two key factors controlling DOC concentration in river flow. As
877 only a small fraction ($< 20\%$) of the riverine DOC is decomposed during lateral transport (Fig.
878 8), the overestimated (Fig. 6) seasonal amplitude in riverine DOC (and TOC) concentrations is
879 likely caused by the uncertainties in the simulated seasonal dynamics of the leached soil DOC.
880 The current scheme used in our model for simulating soil DOC dynamics has been calibrated
881 against observed DOC concentrations at several sites in Europe (Camino-Serrano et al., 2018).
882 Although the calibrated model can overall capture the average concentrations of soil DOC, it is
883 not able to fully capture the temporal dynamics of DOC concentrations (Camino-Serrano et al.,
884 2018). Given this, it is necessary to collect additional observation data on the seasonal dynamics
885 of soil DOC concentration to further calibrate the soil DOC model. In addition, averaged over
886 the various DOC and SOC pools we distinguish in the soils, DOC represents a much more

887 reactive fraction of soil carbon (with a turnover time of several days to a few months) than SOC
888 (with a turnover time of decades to thousands of years). Therefore, soil DOC concentrations
889 experience large seasonal variations, while SOC concentrations generally are much more stable
890 and show very limited seasonal dynamics. Overall, seasonal variations in riverine POC
891 concentrations are mainly controlled by the seasonal dynamics of soil erosion rates, rather than
892 by the seasonal SOC dynamics, which explains a partial decoupling in the behavior of POC
893 compared to that of DOC.

894 Although most processes related to lateral carbon transport have been represented in
895 ORCHIDEE-C_{lateral}, there are still omitted processes and large uncertainties in our model. For
896 example, many studies suggest that a substantial portion of the eroded sediment and carbon is
897 deposited downhill at adjacent lowlands as colluviums, rather than exported to the river (Berhe et
898 al., 2007; Smith et al., 2001; Hoffmann et al., 2013; Wang et al., 2010). As the deposition of
899 sediment and carbon within headwater basins can also significantly alter the vertical SOC profile
900 and soil micro-environments (e.g. soil moisture, aeration and density) (Doetterl et al., 2016;
901 Gregorich et al., 1998; Wang et al., 2015; Zhang et al., 2016), omission of this process may
902 result in uncertainties in the simulated vegetation production and SOC decomposition. In
903 addition, the impact of artificial dams and reservoirs on riverine sediment and carbon fluxes is
904 also not represented in our model. Construction of dams generally leads to increased water
905 residence time, nutrient retention, and sediment and carbon trapping in the impounded reservoir
906 (Habersack et al., 2016; Maavara et al., 2017), and can also affect the downstream flooding
907 regime and frequency (Mei et al., 2016; Timpe and Kaplan, 2017). Estimation by Maavara et al.
908 (2017) suggests that the organic carbon trapped or mineralized in global artificial reservoirs is
909 about 13% of the total organic carbon carried by global rivers to the oceans. To more accurately
910 simulate the lateral carbon transport, we plan to include the soil and carbon redistribution within
911 headwater basins and the effects of dams and reservoirs on riverine sediment and carbon fluxes
912 into our model in the near future.

913 The effects of lateral redistribution of water and sediment on vegetation productivity has not
914 been fully represented in our model. As shown above, our model is able to represent the impacts
915 of lateral water redistribution on vegetation productivity though modifying local soil wetness
916 (Figs. 12 and S16). However, in addition to modifying soil wetness, many studies have indicated

917 that the soil erosion and sediment deposition can affect vegetation productivity by modifying soil
918 nutrient (e.g. nitrogen (N) and phosphorus (P)) availability (Bakker et al., 2004; Borrelli et al.,
919 2018; Quine, 2002; Quinton et al., 2010). Recently, terrestrial N and P cycles have already been
920 incorporated into another branch of ORCHIDEE (i.e. the ORCHIDEE-CNP developed by Goll et
921 al., 2017). By coupling our new branch and ORCHIDEE-CNP, it will be possible to develop a
922 more comprehensive LSM that can also simulate the effects of lateral N and P redistribution on
923 vegetation productivity.

924 Although soils are the major source of riverine organic carbon, domestic, agricultural and
925 industrial wastes, as well as river-borne phytoplankton can also make significant contributions
926 (Abril et al., 2002; Meybeck, 1993; Hoffmann et al., 2020). Moreover, previous studies have
927 shown that sewage generally contains highly labile POC while most of the aquatic production is
928 generally mineralized within a short time (Abril et al., 2002; Caffrey et al., 1998). Omission of
929 organic carbon inputs from manure and sewage could potentially lead to an underestimation of
930 CO₂ evasion from the European river network. Inclusion of these additional carbon sources
931 should thus help improve simulation of aquatic CO₂ evasion.

932 Uncertainties in our simulation results also stem from the forcing data (Table 1) applied in our
933 model. The routing scheme of water, sediment and carbon is driven by a map of stream flow
934 direction at 0.5° spatial resolution (Guimberteau et al., 2012). Comparison between this flow
935 direction map and the flow direction map derived based on high resolution (3") DEM show
936 discrepancies between the two river flow networks (Fig. S6). As the flow direction directly
937 determines the area of each catchment and the route of river flows, errors in forcing data of flow
938 direction may thus induce uncertainties in the simulated riverine water, sediment and carbon
939 discharges. Land-cover maps are another source of uncertainty. For instance, croplands generally
940 experience significantly larger soil erosion rates than grasslands and forests (Borrelli et al., 2017;
941 Nunes et al., 2011; Zhang et al., 2020). However, croplands in ORCHIDEE are only represented
942 in a simplified way by segmenting them into C3 and C4 crops based on their photosynthesis
943 characteristics. Therefore, our simulations based on land cover data with only two broad groups
944 of crop might not be able to fully capture the seasonal dynamics of planting, canopy growth rate
945 and harvesting for all crop types. Furthermore, the effects of soil conservation practices, which
946 would decrease erosion rates, are ignored in our model. Panagos et al. (2015) have shown that

947 contour farming, stone wall and grass margin techniques have been applied in Europe reduce the
948 risk of soil erosion. However, these soil conservation practices only reduce the average erosion
949 rate in European Union by 3%. Excluding soil conservation practices thus should have limited
950 impact in our simulation results.

951 Further model calibration, evaluation and development is necessary for improving our model.
952 Due to the limitation of observation data, we calibrated the parameters controlling sediment
953 transport, deposition and re-detachment (i.e. ω , C_{rivdep} , C_{flddep} , C_{ebed} and C_{ebank} in Table S1) in
954 stream and flooding reservoirs only against the observed sediment yield. Even though our model
955 can overall capture the lateral transfers of sediment and carbon in many rivers in central and
956 northern Europe, more observation data are crucially needed to further evaluate the performance
957 of our model, in particular in southern Europe. In addition, it is still unknown whether our model
958 can satisfactorily simulate intermediate processes such as sediment deposition in river channels
959 and floodplains, as well as the rate of river channel erosion. It is also unknown whether our
960 model would perform satisfactorily in regions with very different climates than Europe such as
961 the tropical region. Thus, in the future, an important aim will be to further calibrate our model
962 against more detailed observation data (e.g. sediment deposition rate in river channels and
963 floodplains) and extend the model application to regions of contrasting climate, vegetation and
964 topography. Moreover, the GLORICH database (Hartmann et al., 2019) only provides
965 instantaneous observations of riverine organic carbon concentrations and it is therefore difficult
966 to evaluate the model's ability to reproduce temporal trends. Therefore, future modelling efforts
967 should be combined with data mining efforts targeting the collection of continuous (e.g. daily)
968 and long-term observational data of organic carbon content and fluxes in streams and rivers.

969

970 **Conclusions**

971 By merging ORCHILEAK (Lauerwald et al., 2017) and an upgraded version of ORCHIDEE-
972 MUSLE (Zhang et al., 2020) for the simulation of DOC and POC from land to sea, respectively,
973 we developed ORCHIDEE- $C_{lateral}$, a new branch of the ORCHIDEE LSM. ORCHIDEE- $C_{lateral}$
974 simulates the large-scale lateral transport of water, sediment, POC, DOC and CO₂ from uplands
975 to the sea through river networks, the deposition of sediment and POC in river channels and
976 floodplains, the decomposition POC and DOC during fluvial transport and the CO₂ evasion to

977 the atmosphere, as well as the changes in soil wetness and vertical SOC profiles due to the lateral
978 redistribution of water, sediment and carbon.

979 Evaluation using observation data from European rivers indicate that ORCHIDEE-C_{lateral} can
980 satisfactorily reproduce the observed riverine discharges of water and sediment, bankfull flows
981 and organic carbon concentrations in river flows. Application of ORCHIDEE-C_{lateral} to the entire
982 European river network from 1901 to 2014 reveals that the average annual total carbon delivery
983 to streams and rivers amounts to $47.3 \pm 6.6 \text{ Tg C yr}^{-1}$, which corresponds to about 4.7% of total
984 NEP and 19.2% of the total NBP of terrestrial ecosystems in Europe. The lateral transfer of
985 water, sediment and carbon can affect the land carbon dynamics through several different
986 mechanisms. Besides directly inducing a spatial redistribution of organic carbon, it can also
987 affect the regional land carbon budget by altering vertical SOC profiles, as well as the soil
988 wetness and soil temperature, which in turn impact vegetation production and the decomposition
989 of soil organic carbon. Overall, omission of lateral carbon transport in ORCHIDEE potentially
990 results in an underestimation of the annual mean NBP in Europe of 4.5%. In regions
991 experiencing high soil erosion or high sediment deposition rate, the lateral carbon transport also
992 changes total SOC stock significantly, by more than 8%.

993 We recognize that ORCHIDEE-C_{lateral} is still entailed with several limitations and significant
994 uncertainties. To address those, we plan to enhance our model with additional processes, such as
995 sediment deposition at downhills or the regulation of lateral transport by dams and reservoirs.
996 We also plan to calibrate and evaluate further our model by extending the observational dataset
997 to regions outside Europe.

998

999 **Code and data availability**

1000 The source code of ORCHIDEE-Clateral model developed in this study is available online
1001 (<https://doi.org/10.14768/f2f5df9f-26da-4618-b69c-911f17d7e2ed>) from 22 July, 2019. All
1002 forcing and validation data used in this study are publicly available online. The specific sources
1003 for these data can be found in section Table 1.

1004

1005 **Author contributions**

1006 HZ, RL and PR designed the study. HZ and RL conducted the model development and
1007 simulation experiments. PR, KV, PC, VN, BG and WY provided critical contribution to the
1008 model development and the design of simulation experiments. HZ conducted the model
1009 calibration, validation and the data analysis. RL, PR, PC, KV and BG provided support on
1010 collecting forcing and validation data. HZ, RL and PR wrote the manuscript. All authors
1011 contributed to interpretation and discussion of results and improved the manuscript.

1012

1013 **Competing interests**

1014 The contact author has declared that neither they nor their co-authors have any competing
1015 interests.

1016

1017 **Acknowledgements**

1018 HZ and PR acknowledges the ‘Lateral-CNP’ project (No. 34823748) supported by the Fonds de
1019 la Recherche Scientifique –FNRS and the VERIFY project that received funding from the
1020 European Union’s Horizon 2020 research and innovation program under grant agreement No.
