10

11 The fire weather index (FWI) is a widely used metric for fire danger based on
12 meteorological observations. However, due to its empirical formulation based on a
13 specific regional relationship between the meteorological observations and fire
14 intensity, the ability of the FWI to accurately represent global satellite-derived fire
15 intensity observations is limited. In this study, we propose a fire parameterization
16 method using feed-forward neural networks (FFNNs) for individual grids. These
17 FFNNs for each grid point utilize four daily meteorological variables (2-meter relative
18 humidity (RH2m), precipitation, 2-meter temperature, and wind speed) as inputs. The
19 outputs of the FFNNs are satellite-derived fire radiative power (FRP) values. Applying
20 the proposed FFNNs for fire parameterization during the 2001–2020 period revealed a
21 marked enhancement in cross-validated skill compared to parameterization solely
22 based on the FWI. This improvement was particularly notable across East Asia, Russia,
23 the eastern US, southern South America, and central Africa. The sensitivity
24 experiments demonstrated that the RH2m is the most critical variable in estimating the
25 FRP and its regional differences via the FFNNs. Conversely, the FWI-based
26 estimations were primarily influenced by precipitation. The FFNNs accurately captured
27 the observed nonlinear correlations between FRP and RH2m, as well as precipitation.
28 In contrast, FWI-based estimations exhibit an excessively negative relationship
29 between FRP and precipitation.

32 forward neural networks

33 **1. Introduction**

34 Fires are inflicting substantial ecological and socio-economic impacts on a global scale.
35 Furthermore, monitoring and managing the risk of fire incidents at an early stage poses
36 a significant challenge for each country (Vitolo et al., 2019). Fire ignitions encompass
37 both natural factors such as lightning, as well as human activities (Jones et al., 2022).
38 After ignition, fire propagation is mainly determined by dryness (Bistinas et al., 2014,
39 Abatzoglou and Williams 2016). Spatially estimating and forecasting dryness enables
40 the monitoring of fire hazards, thus facilitating the implementation of emergency
41 measures to curb the expansion of uncontrollable large fires (Di Giuseppe et al., 2016,
42 Bett et al., 2020, Haas et al., 2022).

43 Among several operational fire danger indices, the fire weather index (FWI)
44 holds a prominent status as an indicator of potential fire intensity. Developed by the
45 Canadian Forest Fire Danger Rating System (Van Wagner 1974, 1987), the FWI is
46 based on four daily meteorological observations: near-surface air temperature, near-
47 surface air relative humidity, wind speed, and precipitation. Fuel moisture codes are
48 first determined from meteorological data to assign numerical ratings to the moisture
49 content of the forest floor and other deceased organic matter. Afterward, fire behavior
50 indices (initial spread index and buildup index) are calculated based on a combination
51 of meteorological observations and fuel moisture codes. Finally, these indices are used
52 to calculate the FWI, thus providing an estimation of fire intensity (Vitolo et al., 2019).

53 Although this system has been shown to be globally applicable (Bedia et al.,
54 2015, Abatzoglou et al., 2018), it was originally developed for the characterization of
55 evergreen pine stands in forested areas of Canada. Therefore, all links between fire
56 moisture codes and fire behavior indices are optimized and parameterized for eastern
57 Canada. However, regional fire dynamics vary significantly depending on vegetation
58 species and their distribution, climatological seasonal cycle, and biogeomorphological
59 characteristics (Ducan et al., 2003, Flannigan et al., 2005, Macias Fauria et al., 2011,
60 Rogers et al. 2015, Kim et al., 2019). For instance, extensive deforestation fires in the
61 Amazon are attributed to insufficient cumulative precipitation (Le Page et al., 2010),
62 whereas Arctic fire activity is more sensitive to temperature (Kim et al., 2020). As
63 reported by Grillakis et al., (2022), each meteorological observation in the FWI system
64 holds varying sensitivity to remotely sensed fire activity.

65 To calibrate the varying sensitivities of the FWI system to meteorological
66 parameters and obtain accurate estimations of fire activity, our study optimized fire

67 parameterizations with satellite-derived fire radiative power (FRP) datasets based on
68 feed-forward neural networks (FFNNs) in each region with fire activity records. Given
69 that FFNNs follow the same structure and input variables as the FWI, the parameter
70 values linking meteorological observations, fire moisture code, and fire behavior
71 indices are established for every $1^\circ \times 1^\circ$ resolution grid box via FFNNs, thus foregoing
72 raw parameterizations in the Canadian FWI. In addition to our novel FFNN-based
73 model, we also conducted an in-depth examination of the FWI-based linear regression
74 model with FRP for comparative purposes. To quantify the relative contributions of
75 each meteorological parameter to the fire parameterizations, sensitivity experiments
76 were conducted based on climatological values of meteorological observations.

77

78 **2. Data and Experimental Design**

79 2.1. Data

80 2.1.1. Fire radiative power (FRP)

81 Given that the FWI was designed to estimate potential fire intensity, our analyses were
82 based on satellite-derived FRP, a metric that represents the rate at which a fire emits
83 energy in the form of thermal radiation. Specifically, daily FRP data was sourced from
84 the Moderate Resolution Imaging Spectroradiometer (MODIS) Collection 6.1 dataset
85 provided by the Fire Information for Resource Management System (FIRMS)
86 (https://firms.modaps.eosdis.nasa.gov/active_fire/) (Giglio et al., 2016). The period of
87 the FRP data spans from 2001 to 2020. The dataset featured a spatial resolution of $1^\circ \times 1^\circ$
88 across the entire globe (0° – 360° E, 90° S– 90° N), with values expressed in megawatts
89 (10^6 J s^{-1} ; MW). It is important to note that although products were generated for both
90 land and ocean areas, we exclusively focused on land values, as FRP is directly
91 associated with fire size and intensity over terrestrial surfaces.

92

93 2.1.2. Meteorological observations

94 Meteorological observations are required as an input of the FWI and the FFNNs for the
95 FRP parameterizations. In this study, we used daily 2 m air temperature (T2m), 2 m air
96 relative humidity (RH2m), 10 m wind speed (WS10m), and precipitation (PRCP) from
97 ERA5 reanalysis produced by the European Centre for Medium-Range Weather
98 Forecasts (ECMWF) from 2001 to 2020 (Hersbach et al., 2020). The original horizontal
99 resolution was a quarter degree but was interpolated to a $1^\circ \times 1^\circ$ resolution over the

100 entire globe (0°–360°E, 90°S–90°N).

101 2.2. Models

102 2.2.1. FWI-based linear regression model

103 A linear regression model was established as a baseline for estimating fire occurrences
104 based on the meteorological variables. This model takes the FWI as its input and yields
105 the FRP as its output. The linear regression coefficient was separately determined for
106 each grid point. The source code to produce the FWI was obtained from the Canadian
107 Forest Service at <https://cfs.nrcan.gc.ca/publications/download-pdf/36461>. A cross-
108 validation strategy was adopted for the skill assessment. For more details, please refer
109 to section 2.3.

110

111 2.2.2. FFNNs for FRP parameterization

112 The FFNNs employed for FRP parameterization consist of one input layer, three hidden
113 layers, and one output layer (Supplementary Fig. S1). The input layer comprises four
114 neurons corresponding to daily measurements of T2m, RH2m, WS10m, and PRCP at
115 a specific grid point. The output layer, on the other hand, encompasses a single neuron
116 responsible for concurrent FRP estimation at the corresponding grid point. Notably,
117 FFNNs are configured individually for each grid point. The first, second, and third
118 hidden layers are composed of 64, 32, and 16 neurons, respectively. Activation
119 functions are implemented utilizing the ReLU function. Techniques such as batch
120 normalization and dropout, with a dropout rate of 0.2, are applied to enhance model
121 robustness. It should be noted that the meteorological observations serving as input for
122 the FFNNs mirror those employed in the FWI. Thus, any disparities in estimation
123 accuracy between the FFNNs and the FWI-based model solely stem from the FRP
124 estimation algorithm.

125 The loss function of the FFNNs is defined as the root-mean-squared difference
126 between the observed FRP (y) and the estimated FRP (\hat{y}) as follows.

127

$$\text{Loss} = \sum_{i=1}^N (y_i - \hat{y}_i)^2$$

128 where N denotes the number of training samples. Similar to the FWI-based model, a
129 cross-validation strategy is adapted for the skill assessment (see section 2.3 for more
130 details).

131

132 2.3. Experimental design

133 The performance of both the FFNNs and the FWI-based linear regression model was
134 assessed by adopting a cross-validation strategy. The dataset was partitioned into
135 distinct subsets for testing, validation, and training purposes. The testing period was
136 defined by dividing the entire period from 2001 to 2020 into three-year intervals. The
137 validation dataset is defined as the last two years of each three-year interval, whereas
138 the remaining data was used for training. For example, for the 2001–2004 test period,
139 the models were trained using a 2005–2018 dataset, whereas the data from 2019–2020
140 was used for validation. Additional details on the selection of periods for training,
141 validation, and testing are provided in Supplementary Table S1. Next, the FRP was
142 estimated using both FFNNs and FWI-based linear regression models across the 2001–
143 2020 period. To assess the FRP estimation accuracy of the evaluation procedures, FRP
144 anomalies were calculated by subtracting the estimated daily climatology throughout
145 the 2001–2020 period.

146

147 **3. FRP parameterization using the FFNNs**

148 Figure 1 illustrates the correlation skill and root-mean-squared error (RMSE) between
149 the observed FRP anomalies from 2001 to 2020 and the FRP anomalies estimated with
150 FFNNs and the FWI-based model. The correlation skill of the FFNNs exceeded 0.6
151 over southern China, northern India, southern South America, the eastern US, southern
152 Africa, western-central Russia, and maritime continents (Figure 1a). In contrast, the
153 correlation skill of the FWI-based model fell below 0.6, with southern China and central
154 Africa being the only exceptions (Figure 1b). Therefore, the FFNNs consistently
155 exhibited superior correlation skills compared to the FWI-based model over most of the
156 globe (Figure 1c). Notably, the improvement in the correlation skill of the FFNNs was
157 statistically significant at a 95% confidence level, as determined using the method
158 outlined by Zou (2007). This significance was particularly pronounced over East Asia,
159 the entirety of Russia, the eastern US, southern South America, and central Africa.

160 The RMSE of the FRP estimations tended to be higher over the regions with high
161 FRP climatology in both models (Laurent et al., 2019). A clear distinction in the RMSE
162 emerges upon comparing FFNNs and the FWI-based model; FFNNs demonstrate an
163 RMSE below 1.5 MW across most regions (Figure 1d), while the FWI-based model
164 predominantly registers RMSE values ranging between 1.5 and 1.8 MW (Figure 1e).
165 Consequently, the global depiction of RMSE differences reveals negative values,

166 illustrating the consistent superiority of FFNNs over the FWI-based model (Figure 1f).

167 The systematic improvement in the accuracy of the estimated FRP using the
168 FFNNs was consistently robust when evaluating the skill evaluation exclusively for the
169 fire events (i.e., observed FRP > 0) (Supplementary Fig. S2) or when considering
170 monthly-averaged FRP anomalies (Supplementary Fig. S3); both daily and interannual
171 variations in estimated FRPs with FFNNs align more closely with the observed FRPs
172 across diverse regions than the corresponding outputs of the FWI-based model
173 (Supplementary Fig. S4). These findings highlight the superiority of FFNNs over the
174 FWI-based model in estimating fire events of varying temporal scales worldwide by
175 successfully exploring the relationship between the FRP and the meteorological
176 observations.

177 To identify the main factors that contributed to the superior accuracy of the
178 FFNNs, sensitivity experiments were conducted by fixing one of the meteorological
179 observations to the daily climatological values (Figure 2). The alteration in correlation
180 skill resulting from controlling each meteorological observation provides a measure of
181 the relative significance of the respective variable in FRP parameterization. The
182 correlation skill remained relatively unaffected when daily climatological values of
183 WS10m or T2m were considered (Supplementary Fig. S5 for the FFNNs, and
184 Supplementary Fig. S6 for the FWI-based model), indicating that the RH2m and PRCP
185 are the main factors influencing the accuracy of the FRP estimations in both models.

186 However, upon further examination, the degree of contribution from RH2m and
187 PRCP to the FRP estimations varied discernibly between FFNNs and the FWI-based
188 model. In the FFNNs, the correlation skill difference between the original estimation
189 and the estimation with the climatological RH2m was close to 0.5 over most of the
190 regions where the original FRP estimations exhibited high skill (Figure 2a). On the
191 other hand, substituting PRCP with its climatological value had a negligible impact on
192 the FFNN-based approach (Figure 2b). Therefore, RH2m was the dominant variable
193 influencing FRP estimations via the FFNNs method over most of the globe except for
194 a few regions (Figure 2c).

195 To support our findings, we adapted the layer-wise relevance propagation (LRP)
196 technique (Bach et al., 2015; Barns et al., 2020; Toms et al., 2020), which is widely
197 used for understanding the relevance of individual features or neurons in neural
198 networks. This analysis consistently validated the significance of RH2m as the most
199 sensitive factor influencing FRP estimation in FFNNs, with the contributions of other

200 meteorological parameters being comparatively minor (Supplementary Fig. S7).

201 Conversely, when employing the FWI-based model, the alteration in FRP
202 correlation skill is more pronounced upon substituting PRCP with its daily
203 climatological values. In regions such as southern China, northern India, southeastern
204 South America, and the eastern US, the correlation skill decrease is between 0.2 and
205 0.3 due to this substitution. In contrast, replacing RH2m with its climatology results in
206 correlation skill differences of less than 0.1 (Figure 2d and 2e). These findings
207 underscore the importance of PRCP as the meteorological variable with the greatest
208 influence on FRP estimation using the FWI (Figure 2f).

209 The dramatic disparity in the relative contributions of RH2m and PRCP between
210 the two models indicates that the factors that drive the predictive performance of the
211 two models were different. Therefore, the relationship between these two key
212 meteorological observations and the FRP estimations will be further explored in the
213 next section to gain insights into the factors that determine the superior performance of
214 the FFNN-based approach.

215

216 **4. Physical explanations of the superior performance of FFNNs**

217 To confirm that the superior performance of the FFNNs is associated with the
218 differences in the relationship between the RH2m and the estimated FRP between the
219 FFNNs and the FWI-based models, we selected grid points that satisfy the following
220 three conditions: (1) an FRP correlation skill improvement in FFNNs over FWI-based
221 models greater than 0.05, (2) RH2m as the most sensitive meteorological variable for
222 FRP estimation in FFNNs, and (3) PRCP as the most sensitive variable in the FWI-
223 based model. A total of 852 grid points were selected based on these criteria, which
224 accounts for approximately 25.1% of total land grid points and 49.7% of total grid
225 points whose correlation skill improvement in the FFNNs is greater than 0.05. The
226 selected grid points are located over southern China, Russia, central Africa, the eastern
227 US, and central-northern South America (Supplementary Fig. S8).

228 Figure 3 illustrates the averaged FRP for each RH2m bin with a 10% interval.
229 Our findings indicated that FRP exhibits a decrease when RH2m surpasses 30% (Figure
230 3a). Therefore, the difference in the FRP values in the higher RH2m bin from that in
231 the lower RH2m bin exhibited negative values (Figure 3b). This relationship reflects
232 the well-known impact of relative humidity on combustion, as oxygen availability is
233 constrained, resulting in reduced combustion rate and lowered FRP (Wooster et al.,

234 2005). Additionally, higher humidity can indicate the presence of moisture in the fuel,
235 such as plants or other vegetation, thereby impeding fire propagation and further
236 decreasing the FRP values.

237 Interestingly, in instances where RH2m falls below 30%, FRP tends to increase
238 with higher RH2m values. Although this proportional relationship between relative
239 humidity and fire activity is relatively uncommon, it can occur following extended
240 periods of drought or low humidity. For example, Abatzoglou and Kolden (2013)
241 reported that this phenomenon can arise when sudden moisture influx induces rapid
242 water uptake by vegetation, thus potentially intensifying fire activity.

243 The FFNNs accurately simulated the aforementioned nonlinear relationship
244 between the RH2m and the FRP (Figure 3c and 3d). In cases where $RH2m < 30\%$, FRP
245 increases with rising RH2m; for $RH2m > 30\%$, FRP diminishes as RH2m rises. The
246 consistency between the estimated and observed FRP values at each bin further
247 supports our previous results, demonstrating the successful application of FFNNs in
248 FRP parameterization.

249 In contrast, the FWI-based FRP estimations exhibit a linear inverse relationship
250 between the RH2m and the FRP. Specifically, FRP decreases continuously with
251 increasing RH2m (Figures 3e and 3f). This unrealistic representation, particularly in
252 dry regimes, demonstrates that the observed nonlinear RH2m-FRP relationship was not
253 faithfully captured in the FWI-based model. Furthermore, the FWI-based estimations
254 tended to overestimate FRP in low RH2m bins (i.e., $RH2m < 30\%$) and underestimate
255 it in high RH2m bins (i.e., $RH2m > 60\%$), which underscores the systematic biases in
256 the FRP estimations in the FWI-based model.

257 Next, we assessed the relationship between PRCP and the FRP values (Figure 4).
258 In both the observed FRP values and those estimated using FFNNs and FWI-based
259 models, PRCP tended to inhibit fire events, causing FRP values to decrease with rising
260 PRCP (Parks et al., 2014; Chen et al. 2014; Holden et al., 2018). In the observational
261 data (Figure 4a), FRP reaches its maximum at 1.9 MW within the lowest PRCP bin (i.e.,
262 $PRCP < 0.1$ mm/day), after which it sharply decreases to approximately 1 MW in the
263 subsequent bin (i.e., 0.1 mm/day $< PRCP < 0.2$ mm/day). Afterward, it experiences a
264 gradual decrease with increasing PRCP when PRCP is below 3 mm/day. However, for
265 PRCP values exceeding 3 mm/day, the extent to which FRP decreases with higher
266 PRCP becomes less pronounced, as higher precipitation does not proportionally reduce
267 ignition likelihood (Oliveras et al., 2014). This leads to sustained FRP values above a

268 certain threshold (i.e., 0.5 MW) for $\text{PRCP} > 3$ mm/day. The spatially averaged FRP
269 distribution in instances where $\text{PRCP} > 3$ mm/day maintains moderate values, ranging
270 from 1 to 2 MW over regions such as Mexico, Colombia, central South America, central
271 Africa, central Western Asia, Australia, and the maritime continent (Figure 4b).

272 FFNNs accurately simulated the observed relationship between the FRP and the
273 PRCP, with the estimated FRP in FFNNs exhibiting high values within the smallest
274 PRCP bins (approximately 1.75 MW), which decreased as PRCP increased when PRCP
275 was below 3 mm/day (Figure 4c). The spatial distribution of the averaged FRP for the
276 cases where $\text{PRCP} > 3$ mm/day was also similar to the observed values (Figure 4d).
277 Conversely, FRP estimation in the FWI-based model tended to be underestimated,
278 particularly in bins with higher PRCP (Figure 4e). For instance, bins with $\text{PRCP} < 0.5$
279 mm/day exhibited an underestimation of approximately 0.25 MW, whereas
280 underestimations of over 0.5 MW, and nearly 0 MW, were evident when $\text{PRCP} > 3$
281 mm/day. This suggests that the FWI-based model is more responsive to changes in
282 PRCP, resulting in a more pronounced FRP decrease with increasing PRCP. This is
283 further evidenced by the spatially averaged FRP distribution for $\text{PRCP} > 3$ mm/day,
284 which is almost negligible worldwide (Figure 4f).

285 This tendency aligns with the quadratic lines fitted to FRP values within each
286 PRCP bin; the quadratic coefficients for observations, FFNNs, and the FWI-based
287 model are 0.022, 0.023, and 0.036, respectively. The heightened FRP sensitivity to
288 PRCP changes in the FWI-based model contributes to the excessive influence of PRCP
289 on the FRP estimations, as shown in Figure 2f.

290

291 **5. Summary and Discussion**

292 In this study, we developed a parameterization method using FFNNs to estimate
293 global gridded FRP fields from meteorological variables. In the FFNNs, four daily
294 meteorological observations, namely 2 m temperature, 2 m specific humidity, wind
295 speed, and precipitation, were used as the input to predict the daily FRP output. The
296 cross-validated FRP parameterization results during 2001–2020 exhibited an improved
297 skill in estimating the observed FRP compared to the FWI-based linear regression
298 model. The improvement in the parameterization accuracy in terms of the correlation
299 skill and the RMSE was observed over most of the globe and was particularly
300 prominent over East Asia, Russia, the eastern US, southern South America, and central
301 Africa. This indicates that FFNNs can more effectively capture the nonlinear

302 relationship between meteorological observations and FRP compared to the commonly
303 employed fire index.

304 A series of sensitivity experiments were performed by replacing each variable
305 with the daily climatological values, and our findings demonstrated that the 2 m relative
306 humidity (RH2m) was the most critical variable influencing the outcomes of the FFNNs
307 over most of the globe. On the other hand, in the FWI-based model, PRCP plays a more
308 substantial role in FRP estimation. The observed nonlinear relationship between the
309 RH2m and the FRP is well simulated in the FFNNs; both the observation and the
310 FFNNs exhibited a negative relationship in the wet regime (i.e., $RH2m > 30\%$),
311 whereas a positive relationship was observed in the dry regime (i.e., $RH2m < 30\%$).
312 Likewise, FFNNs accurately simulated the observed impact of PRCP on FRP reduction.

313 In contrast, the FWI-based model simulated a linear negative relationship
314 between the FRP and the RH2m, which caused systematic errors in estimating the FRP,
315 particularly in the dry regime. Moreover, the FWI-based model exaggerates the degree
316 of FRP reduction with increasing PRCP, which contributes to the stronger contribution
317 of PRCP to the FRP estimations compared to those obtained with the FFNNs. This
318 discrepancy underscores the applicability of FFNNs in understanding the intricate
319 relationship between meteorological observations and FRP, offering insights for
320 refining the algorithm for global FWI calculations. While process-based fire models are
321 valuable for estimating fire activity changes due to greenhouse gas warming, their
322 performance is comparatively less robust compared to empirical models (Rabin et al.,
323 2015; Hantson et al., 2016). Therefore, FFNN parameterizations could enhance
324 process-based land surface models, yielding reliable fire activity predictions and
325 insights into their evolution under greenhouse gas warming scenarios.

326 Current FFNNs solely leverage meteorological observations for FRP
327 parameterization to ensure equitable comparison with the FWI-based model. However,
328 the incorporation of land surface observations such as soil moisture could optimize
329 FFNNs for simulating fire events more effectively. This provides an opportunity to
330 reduce the significant uncertainties in predicting fire events in parameterizing fires in
331 earth system models, ultimately mitigating potential losses from natural hazards.

469

470

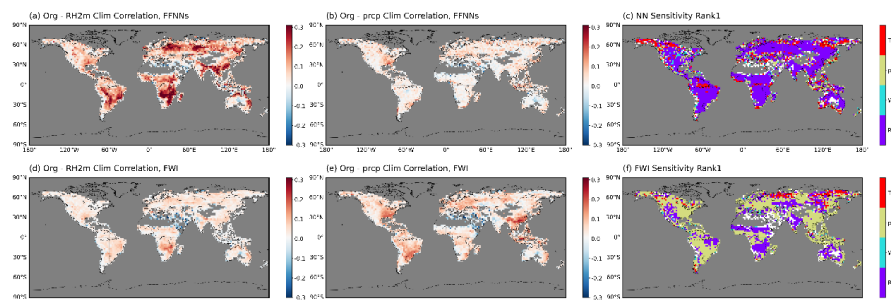

471 Figure 1. Correlation skill between the observed daily FRP and the estimated FRP
472 values in (a) the FFNNs or (b) FWI-based linear regression model during 2001–2020.
473 (c) Difference in the correlation skill in the FFNNs from that in the FWI-base model.
474 RMSEs between the observed daily FRP and the estimated FRP values in (d) the
475 FFNNs, or (e) FWI-based linear regression model during 2001–2020. (f) Difference in
476 the RMSE in the FFNNs from that in the FWI-base model. The dots in panels (a) and
477 (b) denote the grid points where the correlation skill exceeds a 95% confidence level
478 based on the t-test; those in panel (c) denote the area whose correlation skill difference
479 is above a 95% confidence level calculated as described by Zou (2007).

480

481

482

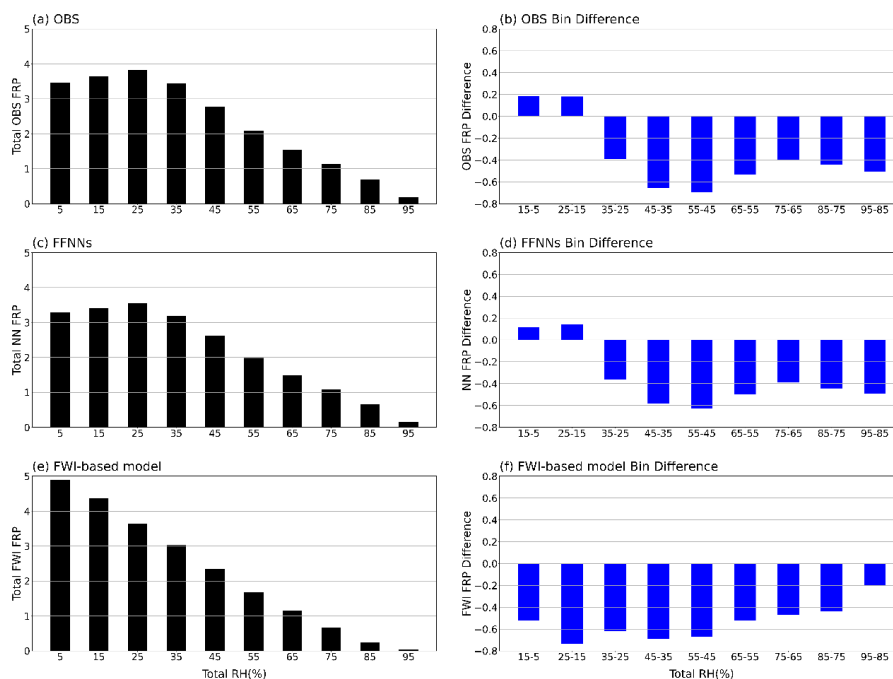

483

484 Figure 2. Difference in the correlation skill of the original FRP estimation in the
485 FFNNs from that by prescribing (a) the RH2m or (b) the PRCP as the daily
486 climatological values. (c) Spatial distribution of the meteorological variable where the
487 decrease in correlation is largest by prescribing the climatological value. Panels (d), (e),
488 (f) are the same as (a), (b), and (c) but for the FWI-based model. In panels (c) and (f),
489 2 m air temperature, PRCP, 10 m wind speed, and RH2m are indicated in red, yellow,
490 green, and purple, respectively.

491

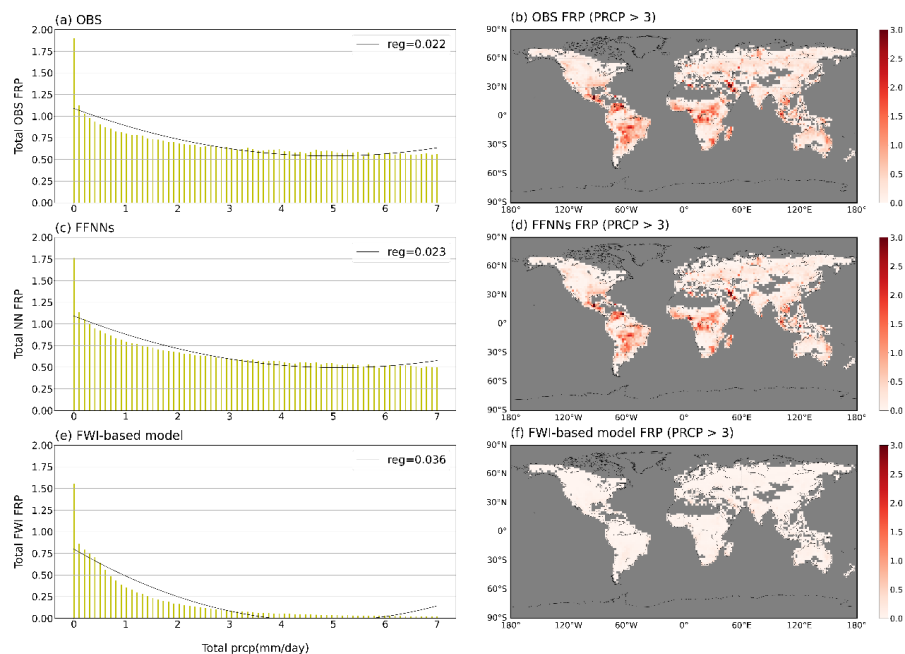

492

493 Figure 3. Case-averaged FRP with respect to the RH_{2m} with a 10% interval in (a)
494 the observations, (c) FFNNs, and (e) FWI-based model. The figures illustrate the
495 difference in the case-averaged FRP at the upper bin from the lower bin in (b) the
496 observations, (d) FFNNs, and (f) FWI-based model. The selected areas for the
497 calculation are shown in Supplementary Fig. S8.

498

499

500

501

502

503

Figure 4. Case-averaged FRP with respect to the PRCP with 0.1 mm/day interval in (a) the observations, (c) FFNNs, and (e) FWI-based model. The figures illustrate the spatial distribution of the case-averaged FRP when the PRCP > 3 mm/day in (b) the observations, (d) FFNNs, and (f) the FWI-based model.
