Short summary (less than 500 characters):

The Indonesia Throughflow is an important pathway connecting the Pacific and Indian Oceans and is part of a wind-driven circulation that is expected to reduce under greenhouse gas forcing. Solar dimming and sulfate aerosol injection geoengineering may reverse this effect. But stratospheric sulfate aerosols affects winds more than simply "shading the sun" and hence reduces the water transport similar as we simulate for unabated greenhouse gas emissions.

Abstract

The Indonesia Throughflow (ITF) is the only low-latitude channel between the Pacific and Indian oceans, and its variability has important effects on global climate and biogeochemical cycles. Climate models consistently predict a decline in ITF transport under global warming, but it has not yet been examined under solar geoengineering scenarios. We use standard parameterized methods for estimating ITF: the Amended Island Rule and Buoyancy Forcing, to investigate ITF under the SSP2-4.5 and SSP5-8.5 greenhouse gas scenarios, and the geoengineering experiments G6solar and G6sulfur that reduce net global mean radiative forcing from SSP5-8.5 levels to SSP2-4.5 levels using solar dimingdimming and sulfate aerosol injection strategies. Six model ensemble mean projections for 2080 - 2100 relative to

29   historical (1980-2014) ITF are reductions of 19% under the G6solar scenario and 28% under the G6sulfur

30   scenario which compare with reductions of 23% and 27% under SSP2-4.5 and SSP5-8.5. Despite

31   standard deviations amounting to 5-8% for each scenario, all scenarios are significantly different from

32   each other ($p<0.05$) when taken over the whole 2020-2100 simulation period. Thus, significant

33   weakening of the ITF occurs under all scenarios, but G6solar closer approximates SSP2-4.5 than does

34   G6sulfur. In contrast with the other three scenarios which show only reductions in forcing due to ocean

35   upwelling, the G6sulfur experiment shows a large reduction in ocean surface wind stress forcing

36   accounting for 47% (38% - 65% across model range) of the decline of ~~total~~Wind+Upwelling ITF

37   transport. There are also reductions in deep-sea upwelling in extratropical western boundary currents.

38

1. Introduction

40   The Indonesian Throughflow (ITF) is an important part of the global thermohaline circulation (Gordon,

41   1986; Lee et al., 2002; Sprintall et al., 2009). The ITF brings about 15 Sv (1 Sv = $10^6\,\mathrm{m^3/s}$; ~10.7 to ~18.7

42   Sv during the INSTANT Field Program, 2004-2006) of warm and fresh water from the Pacific to the

43   Indian Ocean (Sprintall et al., 2009). Since the ITF is the only ocean pathway in the tropics between the

44   Pacific and Indian Oceans it is the key to heat and water volume transport between them (Godfrey, 1996;

45   Talley, 2008). The ITF also plays an important role in regulating global climate and biogeochemical

46   cycles (Ayers et al., 2014; Hirst and Godfrey, 1994), for example the ITF may influence the El Nino-

47   Southern Oscillation (ENSO) by altering the tropical–subtropical exchange, the structure of the mean

48   tropical thermocline, and the mean sea surface temperature (SST) difference between the Pacific warm

49   Pool and the cold tongue, etc. (Lee et al., 2002) and in the supply of iron in the equatorial upwelling,

50   maintaining biological production in the equatorial eastern Pacific (Gorgues et al., 2007). Sen Gupta et

51   al. (2021) used 26 CMIP6 models to predict ITF weakening by 3 Sv (2.4-3.2 Sv model range) under the

52   SSP5-8.5 scenario (the high greenhouse gas emission scenario) relative to 20th century historical means

53   The decline in the ITF would lead to more heat to accumulate in the Pacific Ocean, which could alter

54   tropical atmospheric-ocean interactions and contribute to extreme El Nino /La Nina events (Cai et al.,

55   2015; Klinger and Garuba, 2016).

56

57 The ITF is fed by the Mindanao Current and the New Guinea Coast Undercurrent (Figure 1) and, to a

58 lesser extent, parts of the low-latitude Pacific Western Boundary Current (WBC) that flows toward the

59 equator (Godfrey, 1996; Lukas et al., 1996). The ITF helps supply the Agulhas current leakage from the

60 Indian Ocean to the South Atlantic Ocean, and may be said to flush Indian Ocean thermocline waters

61 southward by boosting the Agulhas current (Durgadoo et al., 2017; Gordon, 2005).

62

63 The interannual and decadal variability of the ITF transport is influenced by surface winds in the Pacific

64 and Indian Oceans (Feng et al., 2011; Meyers, 1996). Wyrtki (1987) noticed that the pressure gradient

65 between the Pacific and Indian Oceans dominates the ITF flux, and hence that sea level is a good indicator

66 of upper-ocean ITF transport. The largest volume flux is in July-August and the lowest in January-

67 February.

68

69 Model simulations consistently project that ITF transport will be weakened by increased greenhouse gas

70 (GHG) forcing (Feng et al., 2012; Hu et al., 2015; Sen Gupta et al., 2021; Vecchi and Soden, 2007). The

71 driving force is the weakening of the Pacific trade winds under global warming in the 21st century which

72 then weaken the Mindanao Current, the main inflow route of the ITF (Alory et al., 2007; Duan et al.,

73 2017; Sen Gupta et al., 2012).

b) Topography of Indonesian Sea
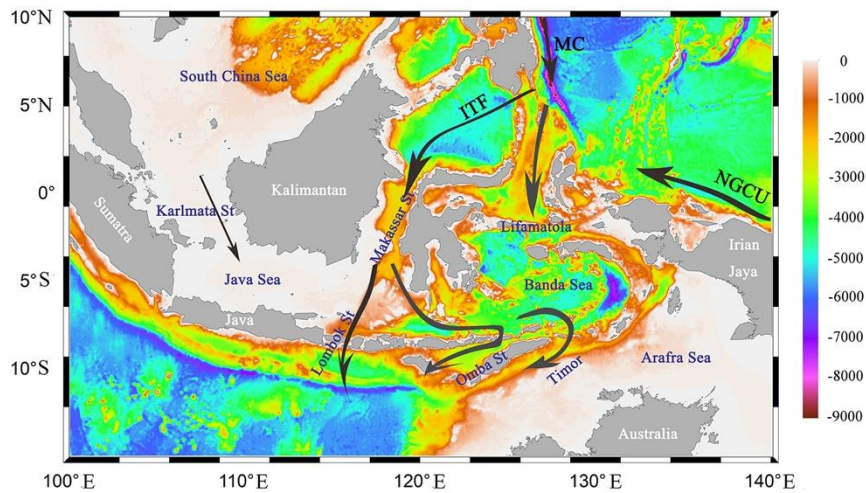

Figure 1. (a) The red line is the wind stress integral path for the Island Rule, The Downstream Buoyant Pool (magenta box) and Equatorial Indian Ocean (blue box) where the density difference is the main index to calculate the ITF transport by buoyance forcing. (b) Inset defined by the cyan dotted line in the panel (a) showing the offshore bathymetry in the maritime continent (ETOPO Global Relief Model, (Amante and Eakins, 2009)) and the Mindanao Current (MC), and the New Guinea Coast Undercurrent (NGCU) paths contributing to the ITF.

Analyzing the water flux through the many shallow channels in the Indonesian archipelago is challenging, and many of these channels are not resolved in simulations with resolutions of a degree or so (Gordon et al., 1999) (Figure 1). This motivates use of alternative methods of estimating ITF. Godfrey (1989) created the Island Rule to estimate flux based on Sverdrup theory (Sverdrup, 1947) analysis of Pacific wind stress. More recently, analysis of climate models revealed the importance of deep ocean circulation to the reduction of ITF transport under GHG forcing. The decline in ITF under GHG forcing could be due

4

to both the weakening of trade winds in the Pacific, and deep ocean circulation changes (Feng et al., 2012; Hu et al., 2015). Interannual to decadal, as well as centennial dependence of the ITF on wind and upwelling was found with an eddy-resolving ocean model simulation (Feng et al., 2017). This led to Sen Gupta et al. (2016), and Feng et al. (2017) proposing the Amended Island Rule that modifies the Island Rule to include the estimated net Pacific upwelling contribution to ITF based on high-resolution (1/10°) ocean general circulation modelling.

An alternative mechanism for the ITF driver was proposed earlier by Andersson and Stigebrandt (2005). In this theory buoyancy forcing is more important than wind forcing in driving the ITF. The ITF variability is found from the baroclinic outflow of the Downstream Buoyant Pool (DBP) that extends over much of the North Australian Basin (Figure 1). Hu and Sprintall (2016) used this method with reanalysis products to produce ITF interannual variability in good agreement with the observed volume transports (2004–2006) from the INSTANT mooring array transport (Sprintall et al., 2009), although the average transport was ~~smaller than~~only half the transport observed ~~transport~~during INSTANT. INSTANT uses moorings deployed at the major inflow (Makassar Strait, Lifamatola Strait) and outflow passages (Lombok Strait, Ombai Strait and Timor Passage) of the ITF to estimate the ITF transport, resulting in a value of 15 Sv during 2004-2006. ~~While the evidence suggests that the Amended Island Rule explains ITF variability better than buoyancy,~~In contrast with the reasonable agreement for the Amended Island Rule estimates of ITF, the alternative buoyancy method behaves much worse, indicating that the hypothetical forcing is not as good an explanation for ITF as the Amended Island Rule, or that the models used do not capture the specific details of the DBP. But although the Amended Island Rule matches the short duration of observed fluxes and variability better than buoyancy, it is possible that changes in buoyancy forcing may affect volume transport of the ITF on decadal scales under a changing climate and so we examine its changes under the geoengineering scenarios.

Solar Radiation Modification (SRM) geoengineering is designed to reduce the solar radiation reaching the surface of the earth and slow down climate warming due to GHG forcing (Shepherd, 2009). Since SRM shortwave forcing has different spatial and temporal variability than longwave forcing, it can only

117 imperfectly offset the climate change caused by the increase of GHGs. In this article we focus on two

118 styles of SRM: reduction of the solar constant to mimic the effect of a sunshade, called solar dimming

119 (SD); and stratospheric aerosol injection (SAI), specifically with injection of sulfate aerosol in the

120 tropical lower stratosphere (Kravitz et al., 2015). These styles of SRM are known to produce over-cooled

121 tropical oceans and under-cooled poles relative to global mean temperatures. However, other styles of

122 injection strategies than the simple tropical site specified by G6 can produce simulated climates without

123 these temperature biases (MacMartin and Kravitz, 2016). Simulated tropical atmospheric circulation

124 systems are impacted under both GHG and solar geoengineering scenarios. Under SD, the seasonal

125 movement of the intertropical convergence zone is reduced relative to GHG climates (Smyth et al., 2017).

126 Both the Hadley and Walker circulations are different from the historical (Cheng et al., 2022; Guo et al.,

127 2018). Impacts of SRM on the Walker circulation are modest compared with the Hadley cell but appear

128 most obviously in relation to the South Pacific Convergence Zone (Guo et al., 2018), which is relevant

129 in the overall tropical Pacific atmosphere system that drives and interacts with the ITF. Greenhouse gas

130 forcing is expected to cause an expansion of the Hadley circulation cells which may be asymmetric

131 between northern and southern hemispheres (Staten et al., 2019). Both SD (Guo et al., 2018) and SAI

132 (Cheng et al., 2022) reduce these greenhouse gas induced changes in the Hadley circulation, although

133 again hemispheric differences remain, and in the Cheng et al. (2022) simulations, were associated with

134 stratospheric heating and tropospheric temperature response due to enhanced stratospheric aerosol

135 concentrations. The changes in stratospheric heating, the tropopause height, and tropical sea surface

136 temperatures may be expected to impact tropical cyclogenesis, and this is consistent with reduction in

137 North Atlantic hurricane numbers and intensity relative to GHG-only climates under SAI (Moore et al.,

138 2015). However, there are differences between tropical basins in expected tropical cyclogenesis potential

139 and significant differences in simulations between climate models (Wang et al., 2018). Potential energy

140 available for extratropical storms is also consistently reduced under SRM relative to GHG

141 forcing(Gertler et al., 2020). The reported impacts highlight the potential role of wind forcing in ITF.

142

143 Little research to date has been done on ocean circulation under SRM, with only the Atlantic Meridional

144 Overturning Circulation (AMOC) having been studied in depth (Hong et al., 2017; Moore et al., 2019;

145   Muri et al., 2018; Tilmes et al., 2020; Xie et al., 2022). Both GHG forcing alone, and with SRM, produce

146   a weakening of AMOC relative to present day, mainly in response to the change of heat flux in the North

147   Atlantic, with little influence from the changes of freshwater flux and wind stress (Hong et al., 2017; Xie

148   et al., 2022). AMOC is less weakened under SRM than with GHG forcing alone and the AMOC declines

149   seen under GHG forcing are consistently reversed by SRM towards present day patterns (Moore et al.,

150   2019; Muri et al., 2018; Tilmes et al., 2020).

151

152   In this study, we will examine the impact of SRM on the change of the ITF in the 21st century, and

153   consider the transport and drivers differences between pure GHG climates representing moderate

154   mitigation (SSP2-4.5) and no mitigation (SSP5-8.5); with solar dimming (G6solar) and stratospheric

155   aerosol injection (G6sulfur) forms of SRM geoengineering.

156

157   **2. Climate Models and Scenarios**

158   The Intergovernmental Panel on Climate Change (IPCC) Shared Socioeconomic Pathways (SSPs) are

159   scenarios defined by radiative forcing goals to be achieved through various climate mitigation policy

160   alternatives (Kriegler et al., 2012; van Vuuren et al., 2011). The climate model simulation results under

161   the SSPs are being performed as part of the Coupled Model Intercomparison Project Phase 6 (CMIP6).

162   We used CMIP6 historical simulation during 1980-2014 (Eyring et al., 2016) and two GHG scenarios

163   during 2015-2100: SSP5-8.5, an unmitigated GHG emission scenario which raises mean global radiative

164   forcing by 8.5 W/m^2 over pre-industrial levels at 2100; and SSP2-4.5 designed to reach peak radiative

165   forcing of 4.5 W/m^2 by mid-century (O'Neill et al., 2016). We use the Geoengineering Model

166   Intercomparison Project Phase 6 (GeoMIP6) G6sulfur and G6solar scenarios during 2020-2100 (Kravitz

167   et al., 2015). The G6sulfur experiment specifies using SAI to reduce the net anthropogenic radiative

168   forcing constantly during the 2020-2100 period from the SSP5-8.5 to the SSP2-4.5 level, while G6solar

169   does the same using SD (Kravitz et al., 2015). The two SRM methods produce significantly different

170   surface climates, with differences from SSP2-4.5 being larger and more spatially variable under G6sulfur

171   than G6solar (Visioni et al., 2021). While the G6 scenarios are not particular realistic, for example they

172   specify starting SAI in 2020 and specify a very simple tropical injection strategy, they do provide a

173 usefully large SRM and GHG signal, and have been simulated by six CMIP6 generation models. This

174 allows more robust findings of the general impacts of SAI, especially when considering aspects of the

175 climate system that have not been addressed to date in geoengineering studies, such as the ITF.

176

177 We used monthly data from the first realization in each scenario from all six Earth System Models (ESM;

178 Table 1) that have performed the CMIP6 and GeoMIP6 scenarios to estimate the ITF transport. The

179 variable fields we use are zonal and meridional wind stress (tauu and tauv), sea water vertical velocity

180 (wo), sea water salinity and temperature (so and thetao) and all). All fields were bi-linearly interpolated

181 (except for sea water vertical velocity, for which we use conservative interpolation) onto a common 0.5°

182 × 0.5° grid.

183

184 **Table 1**

185 *Earth System Models (ESMs) Used in This Study*

Model	Atmospheric Resolution (long × lat)	Ocean Resolution (long × lat)	Reference
CESM2-WACCM	288 × 192	320 × 384	(Danabasoglu et al., 2020)

186

187 **3. Methods**

188 **3.1 Island Rule**

189 In the Sverdrup balance, ocean current acceleration and friction are neglected, and wind stress curl is the

190 driving force of large-scale ocean circulation (Sverdrup, 1947). The "Island Rule" (Godfrey, 1989) uses

191 the Sverdrup balance to calculate the net total flow through a region by the integral of the wind stress on

192 a specific closed path. This is a simple and more efficient way of estimating the long-term magnitude

193 and interannual variability than direct observations of flow through the complex channel topography and

194 equator spanning Indonesian archipelago (Godfrey, 1996). ~~Models have verified that the Island Rule can~~
195 ~~capture the decadal variability of the ITF transport (Feng et al., 2011).~~ Feng et al. (2011) used an eddy-
196 permitting numerical model, ORCA025, to verify that the Island Rule can capture the decadal variability
197 of the ITF transport.

198

199 The original Island Rule assumes that the ocean is dormant below a moderate depth, Z, below which
200 there is no motion (Sverdrup, 1947). The ITF transport is determined by the integral of wind stress along
201 the path from the southern tip of Australia, eastwards to South America, following the coastline to the
202 latitude line of the northwestern tip of Papua New Guinea (PNG) and then traces the west coast of
203 Australia back to the starting point (Figure 1a):

204
$$T_{ITF} = \frac{1}{f_N - f_S} \oint \frac{\tau^l}{\rho_0} dl \tag{1}$$

205 where, f_N and f_S are the Coriolis parameter at the equator and 44°S, respectively. τ^l is the along route
206 wind stress component. ρ_0 is the mean sea water density.

207

208 **3.2 Amended Island Rule**
209 Studies have suggested that a decline in ITF under GHG forcing was due to both the weakening of trade
210 winds in the Pacific, and the impact of the deep ocean circulation change (Feng et al., 2012; Hu et al.,
211 2015). Sen Gupta et al. (2016) used a climate model to attribute GHG-forced decrease of the ITF transport
212 to weakening of deep Pacific upwelling. Feng et al. (2017) estimated the contribution of deep ocean
213 upwelling from the Pacific north of 44°S to produce the Amended Island Rule:

214
$$T_{ITF} = \frac{1}{f_N - f_S} \oint \frac{\tau^l}{\rho_0} dl + \iint_{pacific} w_z \, ds \tag{2}$$

215 where, w_z is the vertical velocity of the Pacific at 1500 m depth. The contribution of deep ocean
216 upwelling is integrated over the whole Pacific north of 44°S (considering volume conservation and the
217 sill depths of the Indonesian seas is less than 1500m). The Amended Island Rule was verified with a near-
218 global eddy-resolving ocean model simulation, and found to well-estimate the interannual to decadal, as
219 well as centennial variabilities of the ITF transport (Feng et al., 2017). Here we describe the ITF using
220 the Amended Island Rule, and its component parts which are the wind driven Sverdrup balance, and the
221 Pacific upwelling.

222

3.3 Buoyancy Forcing

Sea levels in the Pacific and Indian Oceans have been used to estimate the ITF transport in previous studies (Clarke and Liu, 1994; Potemra et al., 1997; Susanto and Song, 2015). Buoyancy accounts for high steric sea level (that is a volume increase due to lower density) in the North Pacific (Stigebrandt, 1984). A pool of low-density water (the DBP) originating in the North Pacific is formed in the eastern Indian Ocean between the Indonesian islands and northwestern Australia (Figure 1a). The sea level drop between Indian and Pacific Oceans occurs essentially at the abrupt eastern boundary of the DBP and is the source of buoyancy forcing (Andersson and Stigebrandt, 2005). In the DBP region, the long-term difference between the westward and eastward transport along the northern and southern flanks of the pool is the ITF transport.

The geostrophic transport in the DBP is related to denser water in the eastern equatorial Indian Ocean (EIO):

$$Q_\lambda = \frac{gH^2\Delta\rho}{2f_\lambda\rho_0} \qquad (3)$$

$$ITF = Q_{\lambda_N} - Q_{\lambda_S} \qquad (4)$$

where, g is acceleration due to gravity, H is the penetration depth of the DBP (set by (Andersson and Stigebrandt, 2005) as 1200 m), f_λ is the Coriolis parameter at latitude λ, ρ_0 is the reference density at 1200 m, The northern (λ_N) and southern (λ_S) boundary latitudes of the DBP are 10°S and 16°S respectively. $\Delta\rho$ is the density difference between the DBP region (9°S–15°S, 100°E–120°E) and the EIO region (6°N–6°S, 80°E–100°E). Hu and Sprintall (2016) verified the use of DPB and EIO to calculate $\Delta\rho$ with observations.

4. Transport and Geoengineering

4.1 ITF Transport

The multi-model ensemble mean wind driven ITF transport is ~16.9 Sv with the Pacific upwelling north of 44°S contributing ~4.5 Sv in the historical period (Figure 2). This compares with observational estimates of about 15 Sv during 2004-2006 (Sprintall et al., 2009) and the multi-model ensemble (total

250   22 CMIP5 models) mean is 15.2 Sv during 1900-2000 (Sen Gupta et al., 2016). Under SSP2-4.5 during

251   2015 - 2100, the wind-driven and Pacific upwelling contributions to ITF transport are not much different

252   from those under SSP5-8.5. The wind driven volume ITF transport has significant trends for all scenarios

253   with smallest trends for the SSP scenarios (linear trends of lower magnitude than 0.02 Sv per year), while

254   the upwelling contributions has obvious downward trends in all scenarios. These trends appear to be

255   consistent, despite differences in estimated transport across models (Figure S1). Thus the decline in future

256   ITF transport in future GHG climates was explained by (Feng et al., 2017) as due to weakening of the

257   Pacific upwelling on centennial timescales while wind-driven processes had no impact on long

258   timescales.

259

260   During the last 20 years of the 21st century, the simulated ITF transport using the Amended Island Rule

261   is 27% ± 3% (standard error) under SSP5-8.5 (Figure 2c), with Pacific upwelling decline accounting for

262   76%±15% (p<0.05, Wilcoxon signed rank test) of the ~~total~~Wind+Upwelling reduction. Both wind driven

263   and upwelling contributions to ITF transport are slightly higher under SSP2-4.5 than under SSP5-8.5

264   during the same period, but the differences are small over the whole 2015-2100 period. The

265   ~~total~~Wind+Upwelling ITF transport is reduced by 23%±2% (standard error, p<0.05) under SSP2-4.5

266   during the period of 2080-2100 relative to the historical period (13%~27% cross ESM range), and with

267   the wind driven component only dropping by 5% (-2%~9% range). The reductions under SSP5-8.5 for

268   upwelling and wind driven components are respectively 97% (60%~305%) and 8% (1%~19%).

269

270   In contrast with the reasonable agreement for the Amended Island Rule estimates of ITF, the alternative

271   buoyancy method behaves much worse. The multi-mean ITF transport simulated by buoyancy forcing is

272   7.3 Sv in the historical period, which is less than that by wind driven and only half the transport observed

273   during INSTANT (Sprintall et al., 2009), and there is large across-model variability (Figure S2). Under

274   the two SSPs scenarios, the difference in ITF transport is small with significant trend during 2015-2100.

275   The buoyancy driven estimation method can capture the interannual variability of ITF transport, but it

276   does not perform well on centennial timescales (Hu and Sprintall, 2016), where ITF is much closer to

277   that from the wind driven estimation method.

278
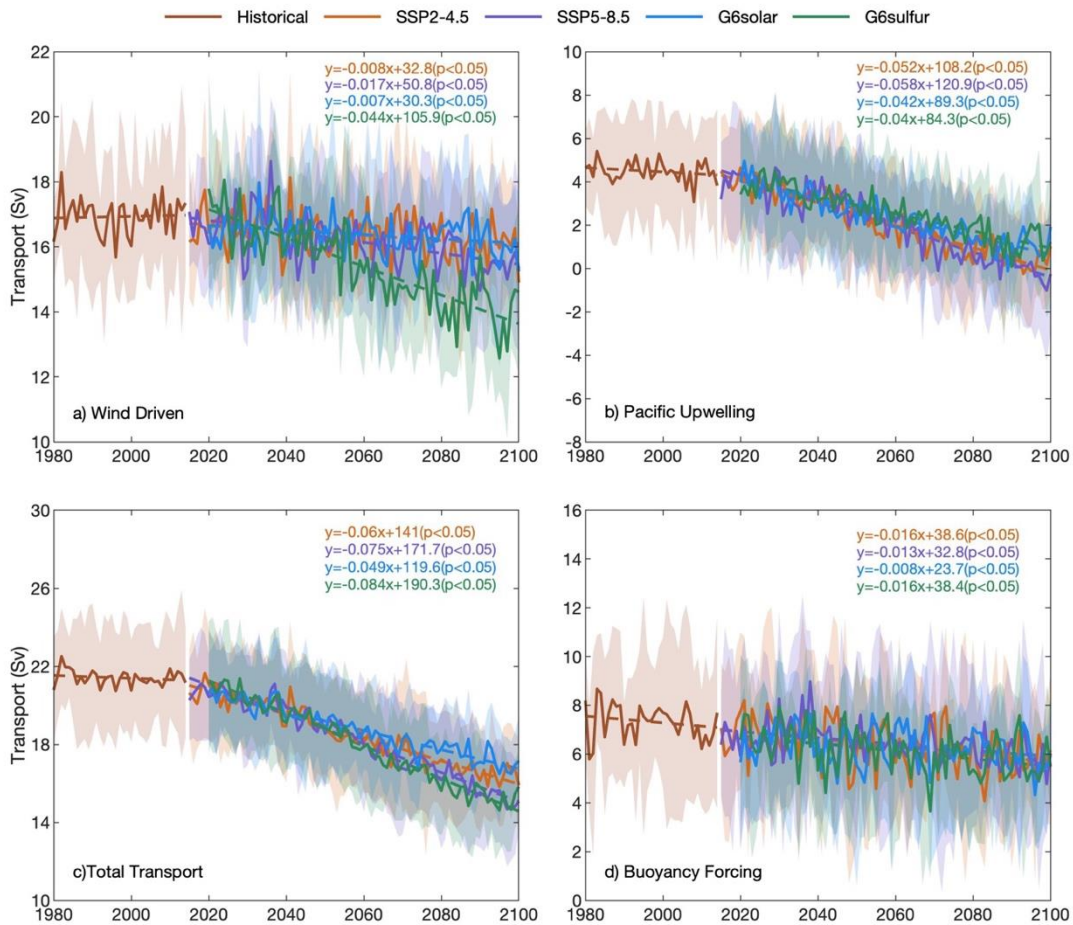

279

280   **Figure 2**. Six ESM ensemble mean ITF components under different scenarios, shadings show the

281   ~~shadings show the~~ standard deviation and the ~~formula is~~equation are the regression trend ~~fitting results~~

282   ~~under different scenarios and the significant value (The ranges are~~ lines (2015-2100 under the two SSP

283   scenarios and 2020-2100 under the two G6 scenarios~~),~~) and the significance of the slope, (a) Sverdrup

284   balance wind driven component. (b) Pacific upwelling north of 44°S. (c) ~~Total~~Wind+Upwelling ITF

285   under the Amended Island Rule (~~eqn~~Eq 2). (d) ITF transport by buoyancy forcing. Individual ESM

286   results are shown in Figure S1.

287

288

289   SAI and SD geoengineering methods clearly have different impacts on wind driven contributions to ITF

290   transport ~~but~~for all models (Table S1) and the ensemble mean (Table 2) according to the Wilcoxon

291   signed- rank test, and smaller although still significant differences in upwelling for the 6 model ensemble

mean, although significant differences individually only for CESM2-WACCM (Figure 2a,b, Table 2; Table S1). Under the G6solar and G6sulfur scenarios, the ~~total~~Wind+Upwelling ITF transport is reduced by 19%±1% and 28%±1% respectively during 2080 - 2100 relative to the historical period, of which the wind-driven ITF transport is reduced by 4%±1% and 16%,±1%, and the upwelling transport volume is reduced by 76%±8% and 70%±10%, all these differences between scenarios are significant (p<0.05~~,~~, Wilcoxon signed-rank test; Table 2~~.~~). Under G6sulfur, the wind driven ITF transport has a clear downward trend in contrast with the other three climate scenarios (Figure 2a). Each ESM also shows consistency in the relative declines under the four future climates (Figure S1a). The decline of wind driven transport accounts for 47% (38% - 65% range) of the decline of ~~total~~Wind+Upwelling ITF transport under G6sulfur during 2080-2100, and its ensemble mean wind driven transport volume is significantly lower than that under SSP5-8.5 (Table 2). The ensemble mean ITF transport by buoyancy forcing all have significant declining trend under the future climate scenarios but the differences are not generally significant (Figure 2d, Table 2), which is different from the transport change calculated using the wind driven and upwelling contributions.

Table 2

The differences in monthly ITF Transport (2020-2100)[a] and its components according to the different methods; Wind is the ITF transport derived from Island Rule and used in the Amended Island Rule; Upwelling is the area integral of Pacific upwelling rate at 1500 m used in the Amended Island Rule; Wind+Upwelling is the ITF transport calculated by Amended Island Rule; Buoyancy is the ITF transport by buoyancy forcing and used independently of the other two components. Unit: Sv (1Sv = $10^6\,\mathrm{m^3/s}$)

| Differences	Wind	Upwelling	Wind+Upwelling	Buoyancy
G6solar – SSP2-4.5	0.02	**0.33**	**0.35**	-0.06
G6sulfur – SSP2-4.5	**-0.96**	**0.53**	**-0.44**	-0.21
G6solar – SSP5-8.5	**0.23**	**0.4**	**0.63**	-0.15

[a]The end dates of the G6solar and G6sulfur of MPI-ESM1-2-HR are 2099 and 2089, respectively, and those of MPI-ESM1-2-LR are both in 2099.   Values in bold are significant at the 95% level according to the Wilcoxon signed-rank test.

318

319

320 The decline in ITF transport via upwelling in future relative to present under all scenarios is illustrated

321 in Figure 3. During the historical period, the zonally integrated, starting at of 44°S and proceeding

322 northward until 60°N, upwelling contributions to ITF transport in the Pacific Ocean steadily accumulate

323 when progressing from southern latitudes until about 20°N. Latitudes further north make little

324 contribution and accumulated upwelling is then fairly constant. This pattern changes in all future climate

325 scenario simulations. The Pacific upwelling contributions to transport volume accumulate steadily, but

326 slower with latitude than under the historical simulation, until to just north of the equator (2°N), and then,

327 after a small decrease rapidly accumulates over a few degrees of latitude. North of 20°N, the integrated

328 upwelling declines. Differences in ocean upwelling velocity under different scenarios are not significant

329 in the Pacific, except in the western boundary current region. Starting from 20°N, the wind stress in the

330 western boundary current region decreases, the upwelling of seawater weakens, (Figure 5), resulting in

331 a reduced upwelling contribution in the future scenario. Between 44°S and 15°S, the zonal cumulative

332 transport curves under SSP2-4.5 and G6solar are relatively similar. The integrated upwelling under the

333 G6sulfur scenario transitions from the smallest of the four future scenarios between 44°S and 20°S to the

334 largest a few degrees north of the equator (Figure 3).

335

336
337 ~~Figure3~~Figure 3. Multi-model ensemble mean zonal cumulative transport by Pacific upwelling north

338 of 44°S during the historical simulation (1980-2014) and under the four future scenarios (2080-2100),

339 shadings show the standard error.

340

341 **4.2 ITF by geoengineering type**

342 **4.2.1Wind stress**

343 Godfrey et al. (1993)suggested that the Indonesian throughflow originates in the South Pacific, where

344 the South Equatorial Current retroflects into the North Equatorial Countercurrent and enters the

345 Indonesian Sea via the Mindanao Current. Wind stress curl is determined by the components of the wind

346 stress vector and drives the ocean circulation (Gill and Adrian, 1982). Figure 4a shows the mean wind

347 stress and wind stress curl in the historical period (1980-2014), and the wind stress curl is positive at low

348 latitudes in the South Pacific, causing mass transport to the north. In the South Pacific under the SSP2-

349 4.5 scenario during 2080-2100, the wind stress curl in the middle latitudes is stronger than in the historical

350 period, while that at low latitudes and along the west coast of South America it is weaker than in the

15

351   historical period (Figure 4a). The SSP5-8.5 scenario anomalies relative to the historical period are similar

352   but extend over a larger region and have larger amplitude (Figure 4b). Net ITF transport volume under

353   SSP5-8.5 is lower than the historical, which is consistent with the difference in wind stress curl between

354   the simulations. There is no significant difference in wind stress curl between G6solar and SSP2-4.5 in

355   mid latitudes, and the difference in low latitudes is relatively small (Figure 4c). The wind stress curl

356   under G6solar is slightly weaker at mid latitudes and slightly stronger at low latitude than with SSP5-8.5

357   (Figure 4d). Differences between wind stress curl under G6sulfur and SSP2-4.5 scenarios are mainly in

358   the mid latitudes, near the equator and the west coast of South America (Figure 4e), which are related to

359   the wind driven ITF transport changes. In contrast, the significant differences between the wind stress

360   curl under G6sulfur and SSP5-8.5 are mainly in the northeast of the South Pacific, and the wind stress

361   curl under G6sulfur is stronger than that under SSP5-8.5 (Figure 4f). The wind stress curl at the inlet of

362   the ITF is significantly weakened under the G6sulfur scenario compared with the two SSPs scenarios.
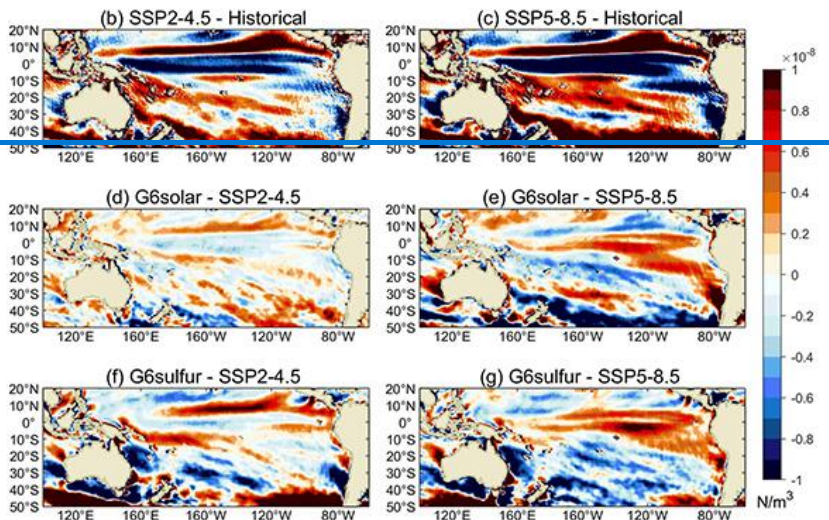

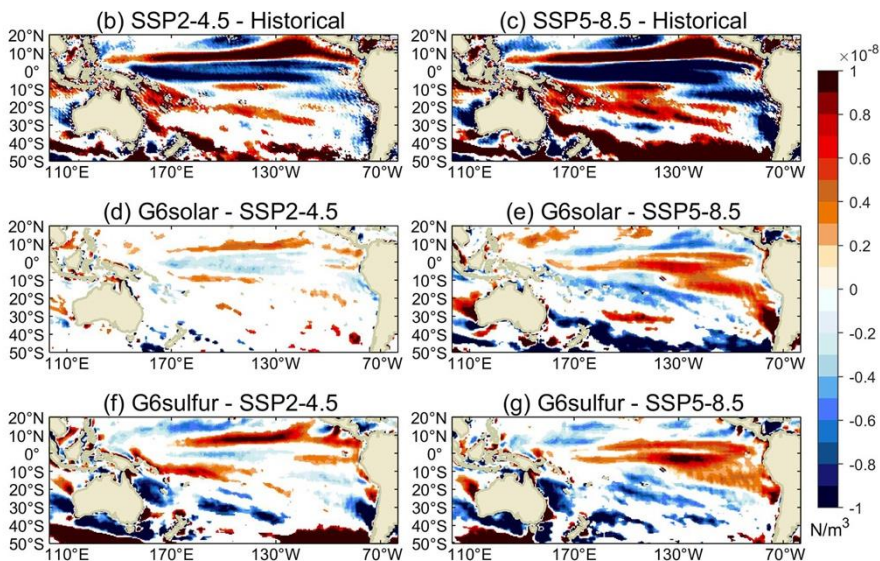

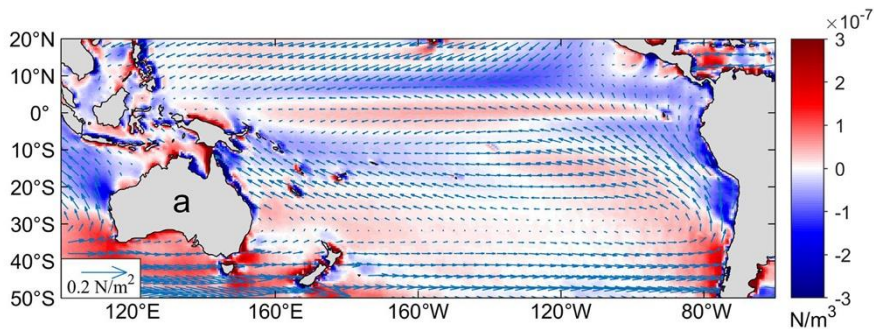

363

364

365

366

367

368

17

369   **Figure 4.** The multi-model mean differences in wind stress curl (a)the historical mean and the arrows

370   show the wind stress, (b) SSP2-4.5 and historical, (c) SSP5-8.5 and historical, (d) G6solar and SSP2-

371   4.5, (e) G6solar and SSP5-8.5, (f) G6sulfur and SSP2-4.5, (g) G6sulfur and SSP5-8.5. The historical

372   period is 1980-2014, and the future scenarios period is 2080-2100. Regions where differences are not

373   significant at the 95% level by the Wilcoxon ~~signed391~~ signed-rank test are masked in white. Fig. S3

374   shows the ITF inlet region around the Indonesian archipelago in more detail.

375

376   The multi-model average ITF transport between G6 scenarios and SSPs scenarios shows significant

377   differences during 2020-2100 (Table 2). Differences in wind-induced ITF transport from SSP2-4.5 are

378   smallest with G6solar (Table 2) and are not significantly different in every ESM (Table S1). Differences

379   between SSP5-8.5 and G6solar are the same sign for wind and upwelling forcings, contributing to larger

380   differences in the amended island rule ~~total~~Wind+Upwelling transport. With G6sulfur, differences in

381   wind and upwelling forcing differences from SSP5-8.5 are oppositely signed, and the net transport

382   difference is quite small, but still significant for the six models ensemble~~.~~ (Table 2). Differences in the

383   ITF defined by buoyancy are only significant for G6sulfur-SSP5-8.5.

395 ~~to the Wilcoxon signed-rank test.~~

396

397 **4.2.2 Upwelling**

398 The spatial pattern of upwelling velocity at 1500 m in the Pacific under present day conditions is for

399 strong upwelling at the equator, weak upwelling in the interior, and mixed up- and down-welling along

400 the ocean boundaries (Feng et al., 2017). In ~~the~~ future greenhouse gas climate scenarios, the main factor

401 affecting ITF transport is net upwelling in the Pacific Ocean (Feng et al., 2017; Sen Gupta et al., 2016).

402 Spatial patterns of upwelling changes are shown in Figure 5.

403

404 Much of the ocean shows no significant changes in upwelling velocity, but the western boundaries differ

405 significantly from the historical in both SSP scenarios (Figure 5a,b), and under SSP5-8.5 there is also a

406 significant upwelling in the equatorial eastern Pacific. The western boundary currents are an important

407 source of ITF gradient differences in wind stress that drive ocean currents (Hu et al., 2015), and these

408 gradients remain present at great depth in the western boundary current region. ~~Much of the ocean shows~~

409 ~~no significant changes in upwelling velocity, but the western boundaries differ significantly from the~~

410 ~~historical in both SSP scenarios (Figure 5a,b), and under SSP5-8.5 there is also a significant upwelling~~

411 ~~in the equatorial eastern Pacific.~~

412

413 The difference of upwelling velocity between G6solar and SSP2-4.5 scenarios is insignificant almost

414 everywhere (Figure 5c~~), while differences~~) once again illustrating the similarities between the solar

415 dimming experiment and its target SSP2-4.5 scenario. Differences from SSP5-8.5 are significant mainly

416 along the extratropical western ocean boundaries. The SAI experiment is clearly different from the solar

417 dimming outcome. G6sulfur differences from the SSP scenarios are clearly larger than those for G6solar~~,~~

418 and are greater in the ~~extratropics~~extra-tropics than in the tropics. The pattern of changes in upwelling

419 anomalies for G6sulfur-SSP2-4.5 is similar but of opposite sign to G6solar-SSP5-8.5 (Figure 5e), while

420 differences for G6sulfur and SSP5-85 are similar or slightly smaller than differences from SSP2-4.5

421 (Figure 5f).

422
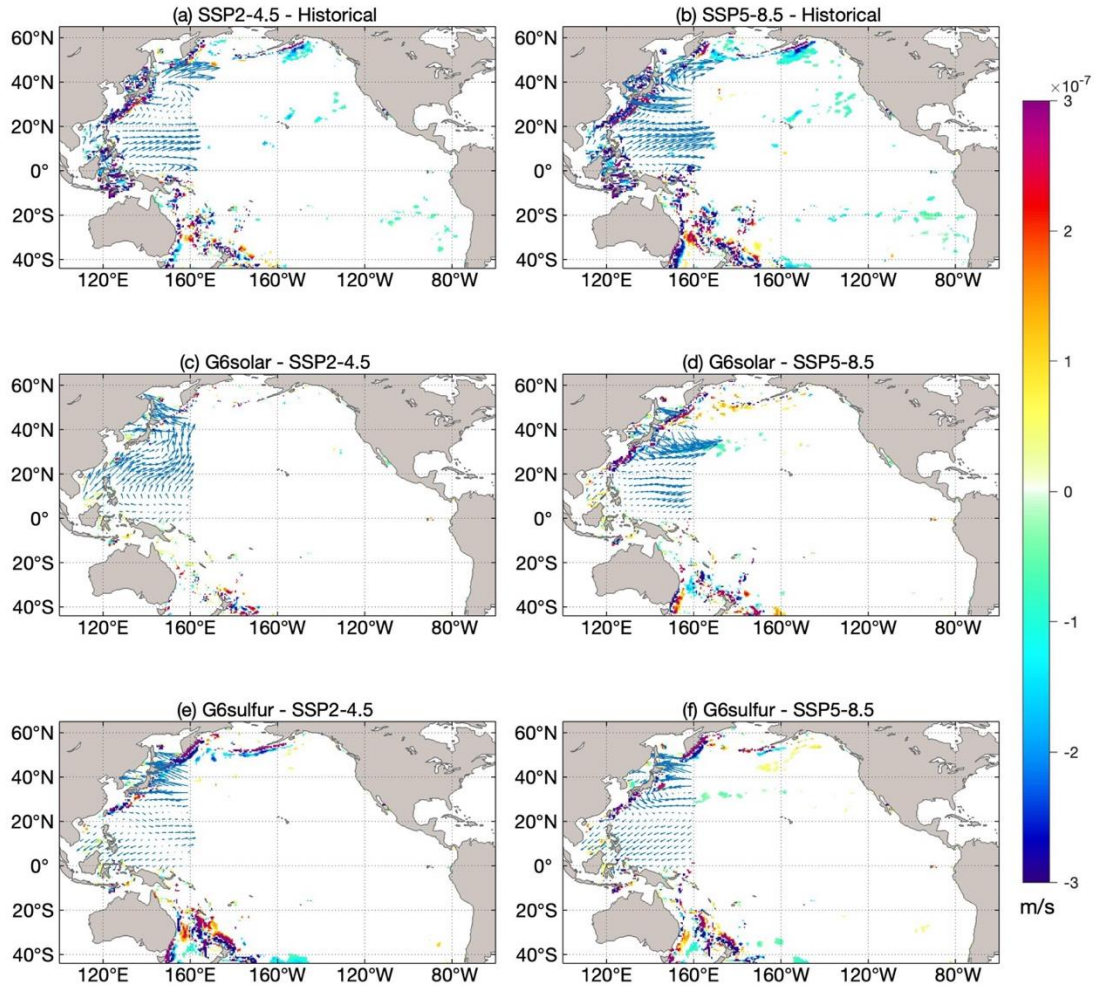

Figure 5. Changes in the multi-model ensemble mean upwelling velocity at 1500m (blue indicates increased upwelling, red indicates relative downwelling) and wind stress difference (arrow) for (a) SSP2-4.5 and historical, (b) SSP5-8.5 and historical, (c) G6solar and SSP2-4.5, (d) G6solar and SSP5-8.5, (e) G6sulfur and SSP2-4.5, (f)G6sulfur and SSP5-8.5. The historical period is 1980-2014, and the future scenarios period is 2080-2100. Regions where differences are not significant at the 95% level by the Wilcoxon signed rank test are masked in white.

4.2.3 Seasonality

Seasonal patterns in ITF are important and reflect changes in position of the two main precipitation convergence zones across the region. Model simulations show that decreases in ITF transport in April-May and October-November, and their recovery are due to the upper ocean changes associated with the Rossby waves in the Pacific Ocean, and that the seasonal ITF transport is closely related to wind

436   variations in the Pacific and Indian Oceans (Shinoda et al., 2012). The seasonal wind-driven ITF transport

437   is maximum in JJA and minimum in DJF under different scenarios (Figure 6), which is consistent with

438   the result by Wyrtki (1987). However, the differences between the G6 scenarios are largest in DJF and

439   MAM, and these seasons are also when all 4 future scenarios are most different from the historical

440   simulation.
441

442   **Figure 6.** The ensemble mean seasonal wind-driven ITF transport and the standard error under the
443   historical period (1980-2014) and future scenarios (2080-2100).

444

445   The South Pacific Convergence Zone (SPCZ) is a strong rainfall and convection zone extending from

446   the equator to the subtropical South Pacific, which is generated by the low-level convergence between

447   the northeast trade wind and weaker westerly wind (Vincent, 1994). The SPCZ is clearest in December-

448   February (DJF), the Southern hemisphere summer, and is marked in the top row of Figure 7. The annual

449   wind stress curl differences between G6solar and SSP2-4.5 are small, but the seasonal variation

450   difference in some regions is significant. Under G6solar, compared with SSP2-4.5, the wind stress curl

451   near the equator is weakened in DJF. In March to May (MAM), the wind stress curl in the middle and

452   low latitudes of the southern hemisphere is generally enhanced. SSP5-8.5 has significantly lower wind

453   stress curl in the SPCZ region relative to G6solar in DJF. In MAM, their differences are mainly in the

454   mid latitudes. From June through November (JJA and SON), wind stress curl under SS5-8.5 is significant

21

455   lowered between 30 °S and 50 ° S. In contrast G6sulfur shows significant increase in the SPCZ region

456   in DJF, and a significant decrease the south of SPCZ region in JJA relative to SSP2-4.5. There are large

457   differences in the ocean northeast of New Zealand with the sign reversing from MAM to JJA. Differences

458   between G6sulfur and SSP5-8.5 are not very much bigger than from SSP2-4.5, and the patterns are quite

459   similar. The wind stress curl in the SPCZ region and its extension southeastwards is significantly

460   weakened under G6sulfur relative to both SSP scenarios in DJF. In JJA the region with decrease in wind

461   stress curl east from New Zealand is slightly larger relative to SSP5-8.5 and SSP2-4.5.

462

463
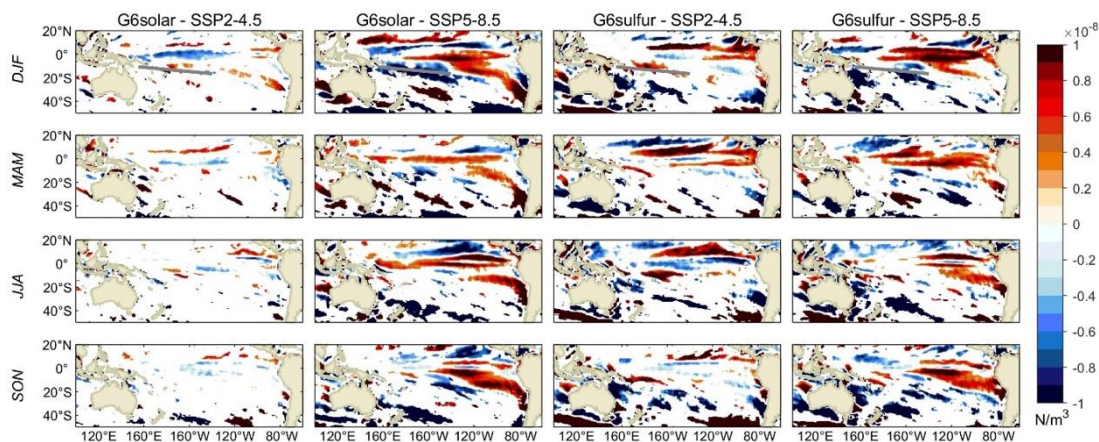

Figure 7. Seasonal ESM ensemble mean spatial differences (G6solar – SSP2-423 4.5, G6solar – SSP5-8.5, G6sulfur - SSP2-4.5, G6sulfur – SSP5-8.5) of the wind stress curl during 2080-2100. The white lines in each panel of the top row marks the mean the position of the South Pacific Convergence Zone (SPCZ) in DJF based on the CMIP6 multi-model mean (Brown et al., 2020). Regions where differences are not significant at the 95% level by the Wilcoxon signed rank test are masked in white, significant differences are larger than $|0.5 \times 10^{-8}|$ Nm^{-3}

470

471

**4.3 ITF and ENSO**

~~5. Summary and Discussion~~

474   The wind driven ITF transport estimated using the six CMIP6 models historical scenario is well within

475   the range of 11-20 Sv, found from 22 CMIP5 models (Sen Gupta et al., 2016). These model estimates

476   tend to slightly overestimate ITF compared with observed ITF (15±3 Sv) since Godfrey's Island Rule

477 ignores friction due to real ocean topography (Feng et al., 2005; Wajsowicz, 1993). The rather large

478 interannual and decadal variations in the ITF (amounting to several Sv) are mainly influenced by the

479 Pacific and Indian Ocean winds. There is an observed relationship between ITF transport and the El

480 Niño-Southern Oscillation (ENSO), with stronger transport during La Niña and weaker transport during

481 El Niña, with ITF variability lagging ENSO variability by 8-9 months (England and Huang, 2005;

482 Meyers, 1996).

483

484 From theWe seek relationships between ITF and ENSO variability using a wavelet coherence analysis

485 (Grinsted et al., 2004) of Nino3.4 and the wind-driven ITF anomaly. This method examines correlations

486 and phase between two time series, and is useful in exploring potential causality relationships (e.g.

487 Grinsted et al., 2004; Xia et al., 2023). Since the models are not adjusted to match observations, the

488 natural variability in the oceans is not synchronized, and so a multi-model ensemble will not show useful

489 phase relationships, so instead we show just the CESM2-WACCM model in Fig. 8, and the other models

490 in Fig. S4. Figs 8 and S4 show obvious annual power is easily seencoherence for all models as could be

491 expected as both time series have clear seasonality, but this is not actually significant against the

492 randomized phase Fourier background hypothesis. There are multi-year significant power episodes in all

493 models, though there are no significant differences in power between the scenarios at any band between

494 annual and decadal. The two appear in anti-phase (Figure 8) in line with observed stronger transport

495 during La Niña and weaker transport during El Niña. At the same time, ITF variability also lags behind

496 ENSO on the whole, but there are differences among different models.

497

498
Figure 8. The squared wavelet coherence between the Nino3.4 (representing ENSO) and the wind-driven ITF transport monthly anomalies under the two SSPs (2015-2100) and two G6 (2020-2100) scenarios in ~~six models.~~CESM2-WACCM model. The 95% significance level above the background of

1000 Monte-Carlo ensemble of series of identical mean and standard deviation with identical power

spectra but phase-randomized Fourier noise (chosen instead of the usual first order autoregressive null

hypothesis here because of the strong annual signal; Xia et al. (2023)), is represented by a thick contour

line. The arrows indicate the relative phase relationship, that is, in-phase points to the right, anti-phase

points to the left, the arrow up indicates that the ITF anomaly leads ENSO by 90°, and a down arrow

indicates that the ITF anomaly lags ENSO by 90°. The other models are shown in Fig. S4.

5. Summary and Discussion

The six ESM we use concur on weakening of ITF transport in all future scenarios. That is SRM cannot

restore the ITF to its historic levels (Table 2, Fig 2). This contrasts somewhat to the changes simulated

in the AMOC under SRM with GHG forcing, where it seems that SRM can partly reverse the slow down

in AMOC induced by GHG forcing, reducing impacts from around 35% to 24% (Muri et al., 2018; Tilmes

et al., 2020; Xie et al., 2022). This illustrates the important regional variability in responses to SRM.

Weakening of the ITF transport appears in all future scenarios, both with pure GHG forcing, and

combining GHG and SRM strategies. The ITF transport changes are defined almost totally (around 90%)

by significant differences in Pacific upwelling (Figure 2a and 2b). This is consistent with the conclusion

that the weakening trend of ITF under global warming predicted by high-precision ocean models is not

directly related to the change of Pacific trade winds but to the reduction of Pacific deep-sea upwelling

(Feng et al., 2017). On centennial scales, the decrease of the net deep ocean upwelling in the tropics and

the South Pacific, especially the changes in the western boundary current system is what determines ITF

transport. Buoyancy forcing can only estimate the interannual variation of the ITF, and our study

supports the utility of the ~~Amened Island Rule in estimating centennial changes in ITF transport.~~

Amended Island Rule in estimating centennial changes in ITF transport. The Island rule was specifically

formulated considering the difficulties in measuring flow in complex topography. Instead, the Sverdrup

theory of wind forcing was utilized, allowing much larger scale observations to provide useful estimates

of ITF. This methodology should also be suitable for the global models we have analysed here. This

contrasts with the relatively small regions of the DBP (Fig. 1), that may not be consistently captured in

the global models we analyze.

532   Sen Gupta et al. (2021) note that projected weakening of the ITF and differences between ESM can be

533   explained by changes in large-scale surface winds. This contrasts with our findings where changes in

534   wind driven transport are not significantly different between models, but instead upwelling in the

535   extratropical western boundary zones dominates changes between scenarios. However, western boundary

536   currents are deep and narrow and differ from the shallow and wide eastern boundary currents. The tropics

537   experience weaker (and reversed) trade winds from those that dominate the extratropical regions. The

538   geographical differences in upwelling suggest that wind changes are driving the overall changes in ITF

539   via upwelling regions, and so in effect supporting the conclusion of Sen Gupta et al. (2021) that

540   differences in future surface winds explain most of the differences in future large scale current systems.

541

542   SSP2-4.5 global radiative forcing was the design target of the G6 experiments despite GHG

543   concentrations being at SSP5-8.5 levels. The difference in wind stress curl between G6solar and SSP2-

544   4.5 indicates that the SD experiment performs better at reversing GHG induced changes in Pacific wind

545   than G6sulfur. The G6sulfur SAI experiment leads to a significant change in the winds in mid and low

546   latitude Pacific Ocean, which results in even lower estimated ITF transport than under the high GHG

547   SSP5-8.5 forcing alone. Furthermore, G6sulfur also impacts deep ocean upwelling especially in the

548   extratropical western boundary current region, such that the ITF transport during the 21st century under

549   the G6sulfur scenario is slower than that under the G6solar scenario. The G6 scenarios do not affect low

550   latitude western boundary currents and upwelling, for example the upwelling near the Mindanao current

551   is unaffected while the upwelling along the Kuroshio current is apparently displaced in both G6

552   experiments. The ITF transport under the SD experiment was stronger than under the SAI experiment

553   and even higher than its target SSP2-4.5 scenario level at the end of the 21st century.

554

555   Changes in circulation in the future will have important impacts on aquatic ecology and fisheries (Dubois

556   et al., 2016). In fact, the population in Indonesia's coastal areas, especially those in the islands through

557   which the ITF passes, are highly dependent on fisheries and hence, the changes in ITF under both pure

558   GHG and mixed GHG and SRM scenarios will have important local implications on the livelihood and

559   ways of life of the local populations. Seasonal variations in ITF transport reflect important processes in

560   the tropical convergence zones, and these are clearly impacted by all 4 future scenarios in generally subtle

561   ways. But the largest differences are seen between the two most challenging scenarios to simulate –

562   SSP5-8.5 and G6sulfur. Despite the large size of perturbation that these forcings apply in the simulations,

563   and the differences between climate models in parameterizing the SAI schemes, the finding are rather

564   robust in the changes of winds in all seasons in the Pacific Ocean and Maritime Continent.

565

566   SAI is a far more feasible method of SRM than SD (Shepherd, 2009), but it produces far larger

567   differences in various climate fields from GHG and historic simulations than does SD (Visioni et al.,

568   2021), and far larger across-ESM differences as the models process the aerosol impacts in varied ways

569   (Visioni et al., 2021). The differences in winds noted in G6sulfur likely arise from differences in

570   stratospheric heating due to the sulfur aerosols that then drive tropospheric circulation changes (Visioni

571   et al., 2020).

572

573   Although ESM can provide reliable predictions of the ITF transport, the accuracy of global meso- and

574   small-scale spatial and seasonal changes remains an issue. These relatively small-scale differences are

575   potentially more important for local impacts than differences in larger scale or annual changes. These

576   aspects will need to be explored using impact models tailored to the region, ideally through initiatives

577   focused on the Global South like the Degrees Initiative (https://www.degrees.ngo/) and addressing

578   concerns raised by local rightsholders.

579

580   **Code and data availability**

581   All model data used in this work are available from the Earth System Grid Federation (WCRP, 2022;

582   https://esgf-node.llnl.gov/projects/cmip6, last access: 3 July 2022).

583   **Author contributions**

584   JCM conceived and designed the analysis. CS collected the data and performed the analysis. CS and

585   JCM wrote the paper. All authors contributed to the discussion.

586   **Competing interests**

587   The contact author has declared that neither they nor their co-authors have any competing interests.
