7 **Abstract.** Ocean heat content (OHC) is a depth-integrated physical oceanographic variable used to precisely measure ocean
8 warming. Because of the limitations associated with in-situ CTD data and Ocean Reanalysis system products, satellite-based
9 approaches have gained importance in estimating the daily to decadal variability of OHC over the vast oceanic region. Efforts
10 to minimize the biases in satellite-based OHC estimates are needed to realize the actual response of the ocean to the brunt of
11 climate change. In the current study, an attempt has been made to better implement the satellite-based ocean thermal expansion
12 method to estimate OHC at 17 depth extents ranging from the surface to 700m. To achieve this objective, ~~an~~-artificial neural
13 network (ANN) ~~models were as~~ developed to derive thermosteric sea level (TSL) from a given dataset of sea surface
14 temperature, sea surface salinity, geographical coordinates, and climatological TSL. The model-derived TSL data were ~~further~~
15 used to estimate OHC changes based on the thermal expansion efficiency of heat. Statistical analysis showed high correlation
16 coefficients and low errors in satellite-derived TSL / OHC ~~of 700 m modeling depth at 700 m water depth~~ (N 388469, R 0.9926
17 / 0.9922, RMSE 1.16 m / 1.56 GJ m⁻², MBE -0.1917 m / -0.2400 GJ m⁻², MBPE -0.4560% / -0.0290%, MAE 0.763 m / 1.029
18 GJ m⁻², and MAPE 2.34% / 0.13%) and nearly similar results at the remaining ~~modeling depths~~. ~~These results suggest that the~~
19 ~~proposed ANN models are capable of generating satellite-based daily OHC maps by covering both shallower and deeper~~
20 ~~oceanic regions of varying bathymetry levels (> 20 m) depth extents. These results suggest that the proposed ANN models~~
21 ~~are capable of accurately estimating OHC changes on real-time data and three-dimensional distribution patterns of depth-~~
22 ~~integrated OHC trends in the global ocean.~~ In addition, the first-ever attempt to estimate the ocean thermal expansion
23 component (*i.e.*, TSL) from satellite data was successful and the model-derived TSL can be used to obtain high-end sea-level
24 rise products in the global ocean.

25 1. Introduction

26 Owing to the ~~vast spatial coverage and high heat capacity~~ ~~vast heat capacity and spatial coverage~~, the oceans balance the
27 planet's temperatures by absorbing ~~89% 93%~~ of the excess atmospheric heat caused by the greenhouse effect and global
28 warming (Abraham et al., 2013; IPCC, 2014; Roemmich et al., 2015; Riser et al., 2016; Trenberth et al., 2016; Meyssignac et
29 al., 2019; ~~Von Schuckmann et al., 2023~~). A precise understanding of the depth-wise penetration of this heat and its

Formatted: Highlight

Formatted: Highlight

Formatted: Highlight

30 accumulation in the upper oceanic layers is **of great importance to the scientific community** ~~inevitable~~ (Liang et al., 2015;
31 Baxter, 2016; IPCC, 2022). Ocean heat content (OHC), a depth-integrated physical oceanographic variable that refers to the
32 amount of heat energy accumulated between any two depths, has gained attention in various studies of the **Earth's Earth** Energy
33 Imbalance (Von Schuckmann et al., 2016; Trenberth et al., 2016; Cheng et al., 2017; Meyssignac et al., 2019; Cheng et al.,
34 2022). Thus, accurate estimation of OHC changes at various depth extents is vital and **is** the motivation of the current study.
35

36 To obtain a complete picture of OHC changes at different depths, the direct measurements of in-situ conductivity,
37 temperature, and depth (CTD) profiles are necessary. These in situ measurements of the ocean properties are limited in terms
38 of depth and spatial coverages, leading to the biased global reconstruction of OHC estimates owing to the sparse measurement
39 data and spatial coverage deficiencies (Jagadeesh et al., 2015; Meyssignac et al., 2019; Marti et al., 2022). However, the in-
40 situ CTD profile measurements have been used to develop and validate the different OHC models (Momin et al., 2011;
41 Jagadeesh et al., 2015; Su et al., 2020; Prakash and Shanmugam, 2022). **On the other hand** ~~In addition~~, synthetic CTD profile
42 data generated by the Ocean Reanalysis systems (ORA) have been used to ~~study~~**compute** OHC variability in spatial and
43 (Balmaseda et al., 2015; Palmer et al., 2017). More recently, satellite-based methods have become crucial **to overcome the**
44 **limitations associated with in-situ CTD data and Ocean Reanalysis system products** ~~to overcome the limitations in the in-situ~~
45 and to understanding the evolution of the Earth's climate system (Meyssignac et al., 2019; Prakash and Shanmugam, 2022).

46 **The existing satellite-based OHC algorithms can be broadly grouped into three approaches based on the employed**
47 **principles/parametrizations: (i) internal tide oceanic tomography (ITOT), (ii) ocean net surface heat fluxes, and (iii) ocean**
48 **thermal expansion. Apart from these approaches, research is exploring ways to make use of tidal magnetic satellite observations**
49 **(Irrgang et al., 2019), electrical conductance (Trossman and Tyler, 2019), and atmospheric oxygen & carbon dioxide**
50 **concentrations (Resplandy et al., 2018) to infer OHC changes. The ITOT technique involves correlating the satellite altimeter-**
51 **derived internal tide phase changes with ocean warming to estimate the OHC variability. This technique is still at the proof-**
52 **of-concept level and the associated challenges remain to be addressed (Zhao, 2016a, 2017; Meyssignac et al., 2019). The OHC**
53 **estimation through the ocean net surface heat fluxes employs several assumptions and approximations in deriving the input**
54 **parameters to compute the radiative and turbulent heat fluxes, which in turn leads to higher uncertainty in global OHC changes**
55 **(Wild et al., 2015; L'Ecuver et al., 2015; Meyssignac et al., 2019).**

56 **On the other hand, the ocean thermal expansion method is a promising technique for the estimation of OHC by**
57 **considering the thermosteric sea level (TSL) and expansion efficiency of heat (EEH). Numerous satellite-based OHC models**
58 **have been developed based on the sea surface height anomaly data from altimeters, water mass change equivalent sea level**
59 **anomaly data from the Gravity Recovery and Climate Experiment mission (GRACE), sea surface temperature from the various**
60 **radiometers onboard satellites, and wind speed/stress from scatterometers/numerical weather models. Pioneering work done**
61 **by White and Tai (1995), Chambers et al. (1997), Polito et al. (2000), and Sato et al. (2000) have attempted to implement the**
62 **ocean thermal expansion method based on a relationship between OHC and satellite altimeter-based sea surface height anomaly**
63 **(SSHA). It should be mentioned that regardless of the source, the volume of seawater changes when it is subjected to**

64 heating/cooling, and it eventually reflects in sea surface topography. The SSHA data recorded by the satellite altimeters
65 comprise the sea surface topography changes due to tides, atmospheric pressure, salinity (haline), and barotropic flows along
66 with the thermal effects. The SSHA changes due to the tides and atmospheric pressure can be corrected, but the effects of
67 salinity and barotropic flows remain unresolved with the OHC estimates produced by Wang and Tai (1995) and Chambers et
68 al. (1997). Sato et al. (2000) have introduced a haline correction factor as the integral product of the haline contraction
69 coefficient and salinity anomaly from in-situ CTD profile data. Owing to the limitations associated with in-situ data, the in-
70 situ-based haline correction cannot be applied to satellite altimeter-based SSHA data while correlating with the space and time-
71 varying OHC data. Jayne et al. (2003) have proposed the Alt-GRACE approach to resolve the effect of barotropic flows in sea
72 surface topography by subtracting the satellite gravimetry-derived water mass change component from SSHA data. Though
73 the Alt-GRACE approach has improved the accuracy of satellite-based OHC estimates compared to Wang and Tai (1995),
74 Chambers et al. (1997), Polito et al. (2000), and Sato et al. (2000), the issues associated with the haline effects and other
75 approximations on the ocean thermal expansion coefficient and seawater density data have led to significant uncertainties in
76 satellite-based OHC estimates.

77 With the advancement of artificial intelligence, several researchers have attempted to model OHC by directly relating
78 it with the satellite-based parameters of relevance by using deep-learning regression techniques (Jagadeesh and Ali, 2006;
79 Momin et al., 2011; Chacko et al., 2015; Jagadeesh et al., 2015; Su et al., 2020, 2021; Marti et al., 2022; Lyman and Johnson,
80 2023). These deep-learning models have oversimplified the OHC problem by neglecting the effects of salinity and barotropic
81 flows. In addition, no previous work have accounted for the space and time-varying nature of the ocean thermal expansion
82 coefficient and seawater density in OHC computations. The other common drawbacks with the existing work are discussed in
83 Sect. 4.3. Consequently, there is a need for developing a satellite-based model to accurately implement the ocean thermal
84 expansion method to estimate OHC by resolving all the issues associated with salinity variation, barotropic flows, ocean
85 thermal expansion, seawater density, choice of temperature and its units.

86 Given the above background, we have made a major attempt to develop and implement the satellite-based ocean
87 thermal expansion models for estimating OHC changes at various depth extents (such as 20 m, 30 m, 40 m, 50 m, 100 m, 150
88 m, 200 m, 250 m, 300 m, 350 m, 400 m, 450 m, 500 m, 550 m, 600 m, 650 m, and 700 m). It enables the research community
89 to generate satellite-based OHC maps of varying bathymetry levels (≥ 20 m) by covering both shallower and deeper oceanic
90 waters. For this, artificial neural network (ANN) architectures were developed to estimate TSL for the given sea surface
91 temperature (SST), sea surface salinity (SSS), geographical coordinates, and climatological TSL. The model-derived TSL
92 estimates were then used to estimate OHC changes by accounting the expansion efficiency of heat. The proposed models are
93 capable of estimating TSL and OHC accurately at multiple depth extents. The robustness of the new models was tested by
94 comparison of model-derived TSL and OHC with in-situ data. The existing satellite-based OHC algorithms can be broadly
95 grouped into three approaches based on the employed principles/parametrizations: (i) internal tide oceanic tomography (ITOT),
96 (ii) ocean net surface heat fluxes, and (iii) ocean thermal expansion. Apart from these approaches, research is exploring ways
97 to make use of tidal magnetic satellite observations (Irrgang et al., 2019), electrical conductance (Trossman and Tyler, 2019),

98 and atmospheric oxygen & carbon dioxide concentrations (Resplandy et al., 2018) to infer OHC changes. The ITOT technique

99 2. Data

100 2.1. In-situ data for model development and in-situ validation

101
102 NOAA's National Centers for Environmental Information Data Archive for the period of 2005-2020 (Boyer et al., 2018a).
103 These data have been extensively used by the research community for various ocean applications (Levitus et al., 2009; Momin
104 et al., 2011; Levitus et al., 2012; Cheng et al., 2014; Roemmich et al., 2015; Jagadeesh et al., 2015; Su et al., 2020). The World
105 Ocean Database (WOD) comprises the oceanographic data of diverse biogeochemical parameters that have been collected by
106 various institutions, agencies, individual researchers, and data recovery initiatives. The quality-controlled CTD profile data
107 (*accepted_value* flag) of standard depth levels recommended by the International Association of Physical Oceanography
108 (1936) were considered in this study to compute the TSL_d and OHC_d parameters and to obtain the SST and SSS data. The
109 standard depth levels considered for deriving the TSL and OHC are given as 20 m, 30 m, 40 m, 50 m, 100 m, 150 m, 200 m,
110 250 m, 300 m, 350 m, 400 m, 450 m, 500 m, 550 m, 600 m, 650 m, and 700 m. The in-situ TSL_d and OHC_d parameters were
111 computed by applying the integration **formulae** (Eqs. 1 & 2) on the CTD profile data of depth range from the ocean surface to
112 the respective standard depth (d) **and the corresponding SST and SSS values were extracted, as well as the SST and SSS data**
113 **corresponding to the ocean surface.** Similarly, the climatological parameters such as $TSL_{clim,d}$ and $OHC_{clim,d}$ were computed
114 from the monthly climatological temperature and salinity data of 41 vertical levels obtained from the World Ocean Atlas-2018
115 (WOA) (Boyer et al., 2018b). The theoretical considerations **for** computing OHC change at a depth can be found in Prakash
116 and Shanmugam (2022) (Prakash and Shanmugam, 2022), **and the same were which were** adopted in this study. The Gibbs-
117 SeaWater (GSW) Oceanographic Toolbox of TEOS-10 (IOC et al., 2010) was used to compute the in-situ-based parameters
118 including

$$119 OHC_d = \int_0^d \rho C_p \theta dz \quad (1)$$

$$120 TSL_d = \int_0^d \alpha \theta dz \quad (2)$$

121 where OHC_d refers to the heat energy accumulated in an oceanic layer of depth range from the surface to a stipulated depth
122 (d) and is given in the units of joules per unit area ($J m^{-2}$). Similarly, TSL_d (in meters) refers to the thermosteric sea level
123 integrated from the surface to a stipulated depth (d). And, θ is the conservative temperature in K (derived from in-situ
124 temperature, absolute salinity, and pressure), ρ is the seawater density in $kg m^{-3}$ (derived from the conservative temperature,
125 absolute salinity, and pressure), C_p is the specific heat capacity ($= 3991.87 J kg^{-1} K^{-1}$), and α is the thermal expansion coefficient
126 in K^{-1} (derived from the conservative temperature, absolute salinity, and pressure).

127 Python programming was used to prepare the individual databases for all the standard depth levels by extracting CTD
128 profile data from the WOD and WOA NetCDF files with the help of NetCDF4, NumPy, Pandas, and GSW libraries. **Each**

129 database (in-situ OHC, in-situ TSL, in-situ SST, in-situ SSS, climatological OHC, climatological TSL, and WOA geographical
130 coordinates) was divided into two datasets, one for the model development spanning from 2005-2016 and one for (in-situ
131 based) validating the model spanning from 2017-2020, by ensuring a well distribution in spatiotemporal scales over the global
132 open ocean. Each database was divided into two datasets, one for the model development spanning from 2005-2016 and one
133 for validating the model spanning from 2017-2020, by ensuring a well distribution in spatiotemporal scales over the global
134 open ocean. The spatial distribution of data points used to model TSL₇₀₀ and OHC₇₀₀ is shown in Fig. A1. The in-situ CTD
135 profiles of depth coverage shallower than 700 m are also included in this process of deriving the TSL and OHC of other depth
136 extents. Indeed, the number of CTD profiles and their distribution in global oceans is higher than the CTD profile density as
137 shown in Fig. A1.

138 2.2. Satellite-based validation

139 For the validation period 2017-2020, the NOAA Advanced Very High-Resolution Radiometer (AVHRR) Optimum
140 Interpolation Sea Surface Temperature products (OISST v2.1) were used for daily SST data of 0.25° spatial resolution (Huang
141 et al., 2021). Daily SSS data of the same spatial resolution were obtained from the ORAS5 Ocean reanalysis system of the
142 European Centre for Medium-Range Weather Forecasts at the CMEMS portal (Product ID:
143 GLOBAL_REANALYSIS_PHY_001_031) (Zuo et al., 2017). The NetCDF4 and NumPy Python libraries were used to read
144 and resample satellite data to the WOA-18 grid, and to collocate with the corresponding Argo in-situ data points. The accuracy
145 of the satellite-based SST and ORA-based SSS was verified by Argo-measured SST and SSS data (N = 244722). The observed
146 R, RMSE, MBE, and MAE values in SST & SSS validations are 0.99 & 0.99, 0.51°C & 0.26 PSU, -0.05°C & -0.006 PSU
147 and 0.33°C & 0.12 PSU, respectively. High correlation coefficients and low errors indicate the minimal deviation of satellite-
148 based data from the actual (in-situ) data and ensure the reliability of satellite data in accurately representing the physical
149 oceanographic conditions.

150 3. Methodology

151 3.1. Theoretical formulations

152 Ocean thermal expansion is the best proxy to model the heat content accumulated in an oceanic layer. Unlike freshwater,
153 seawater expands when it warms and contracts when it cools ~~to~~for temperatures above its freezing point. The volumetric
154 expansion of seawater is non-isotropic in nature due to the differences in the degree of constraint in different directions. In a
155 vertical direction, atmospheric pressure exerts a normal force on the seawater parcel at the surface. The magnitude of this
156 normal/vertical force is less compared to the horizontal forces exerted by physical barriers such as continental boundaries and
157 geographic features on the ocean floor. It allows the ocean thermal expansion of seawater in the vertical direction rather than
158 the horizontal direction, as the seawater is less constrained in the vertical direction compared to the horizontal direction. The
159 amount of change in seawater volume in response to the net warming/cooling depends on the absolute conservative temperature

160 and ocean thermal expansion coefficient (Eq. 2). Following are the GSW functions (Eqs. 3-5) (IOC et al., 2010) involved in
 161 the calculation of TSL (Eq. 2) for the given set of measured temperature (T), practical salinity (SP), pressure (P), longitude
 162 (x), and latitude (y).

$$163 \text{ Absolute salinity (SA)} = gsw.SA_from_SP(SP, P, x, y) \quad (3)$$

$$164 \theta = gsw.CT_from_T(SA, T, P) \quad (4)$$

$$165 \alpha = gsw.Alpha(SA, \theta, P) \quad (5)$$

166 Hence, an attempt has been made in this study to model TSL as a function of SST, SSS, and geographical coordinates. The
 167 existing correlations between the proposed input parameters and the targeted output parameter were explored by employing
 168 in-situ-based data used in the model development process (Fig. 1).

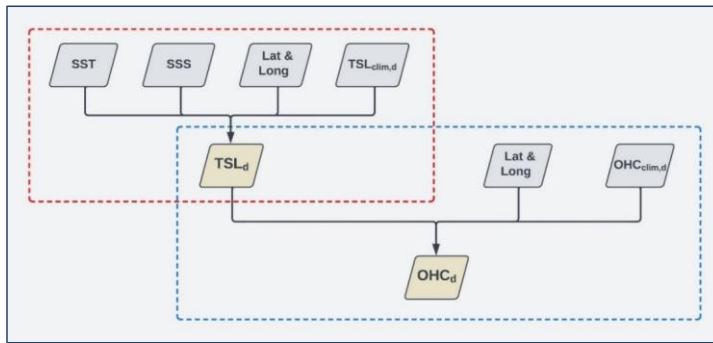

169
 170 **Figure 1.** Heatmap showing the Pearson correlation coefficients between the input parameters (*i.e.*, SST, SSS, and
 171 geographical coordinates) and the output parameter (TSL) of various depth extents.

172 It is observed that SST has an almost one-to-one correlation with TSL at shallower depth extents, and can be solely
 173 used to model the thermal expansion of upper oceanic layers. Despite a decreasing trend in correlation strength when moving
 174 towards **deeper depths**, SST plays a primary role in accounting for TSL variations at deeper depths, because of its strong
 175 correlations with TSL. Observed weaker correlations between SSS and TSL which are plausible owing to the salinity's
 176 secondary role in TSL variations as compared to the temperature variable. However, an increasing trend in correlation
 177 coefficients between SSS and TSL is observed towards the deeper depth extents. Hence, SST and SSS are complementary to
 178 each other in resolving the TSL variations, and their combination plays a major role in modelling TSL of all depth extents
 179 considered in this study. Apart from these physical parameters, absolute salinity used in the computation of seawater density,
 180 conservative temperature, and ocean thermal expansion coefficient is a function of geographical coordinates along with
 181 practical salinity and pressure (Eq. 3). By considering all these theoretical considerations and observed correlations, an attempt
 182 has been made to model TSL of various depth extents by employing SST, SSS, and geographical coordinates as the input
 183 parameters along with the climatological TSL (Fig. 2). Here, TSL_d is an external manifestation of OHC_d stored in an oceanic
 184 layer based on EEH_d (Eq. 6). The model-derived TSL is further used to estimate OHC changes (as shown in Fig. 2 along with
 185 climatological OHC) as follows,

$$186 OHC_d = \frac{TSL_d}{EEH_d} \quad (6)$$

187 where EEH is a conversion factor that explains the relationship between the relative changes in ocean heat content and the
 188 corresponding seawater thermal expansion. As it varies as a function of temperature, salinity, and pressure, EEH is not a
 189 constant value over the global ocean. Hence, ANN modelling is employed in this study to derive OHC from TSL by accounting
 190 the complex variations in EEH .

191
 192 **Figure 2.** Flow chart representing the parameters involved in TSL and OHC modelling. The red and blue dashed boxes
 193 represent the TSL and OHC frameworks employed in ANNs, respectively.

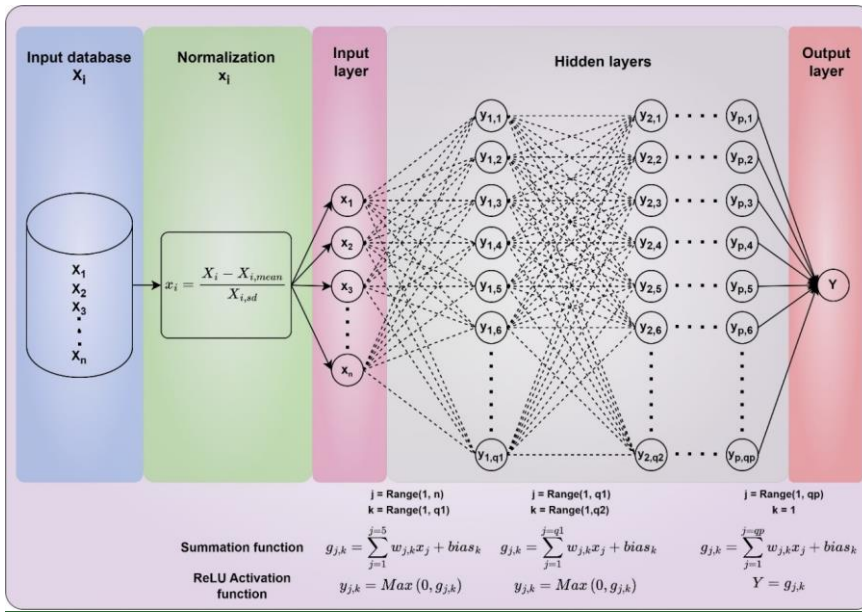

194

195 3.2. ANN model description

196 This section explains the various steps and architectures involved in the ANN modelling of TSL and OHC. The multilayer
 197 perceptron regressor algorithm of deep neural networks was used to model both TSL and OHC (Pedregosa et al., 2011). It is
 198 observed that the input data of geophysical parameters are given in different units and scales. The range and order of SST,
 199 SSS, latitude, and longitude data are $-1.8\text{ }^{\circ}\text{C}$ to $34.15\text{ }^{\circ}\text{C}$ & $O(10^1)$, 2.53 PSU to 40.45 PSU & $O(10^1)$, -76° to 80° & $O(10^1)$,
 200 and -180° to 180° & $O(10^2)$, respectively. In addition, the range and order of $TSL_{clim,d}$ and $OHC_{clim,d}$ are also distinct and vary
 201 with water depth. Hence, the input data were normalized using the StandardScaler class of Scikit-Learn and feed-forwarded
 202 through the neural networks. This StandardScaler normalizes the raw data to ensure the mean and standard deviation of each
 203 input parameter as 0 and 1, respectively. It allows the ANN model to focus on the relative importance and relationships between
 204 the input parameters rather than their magnitude. The standardized input data were injected into the corresponding neurons in
 205 the input layer and forward propagated through the hidden layers and then the output layer by applying the random weights
 206 and rectified linear unit (ReLU) activation function at each neuron (Fig. 3). The mathematical formulations and schematic
 207 representation related to ANN architecture are shown in Fig. 3. The model outputs were compared with the actual data and
 208 computed mean squared error (MSE) using a loss function (Eq. 7). In addition, L2 regularization (α_{L2}) was employed to add
 209 a penalty term to the loss value to prevent overfitting. The observed error was then backpropagated through the network to
 210 update weights and biases using the Adam optimizer based on the learning rate and gradient of the error (see Eq. 8 in Prakash
 211 and Shanmugam, 2022). This process is repeated until the validation score improves more than 0.0001.

212
$$MSE = \frac{1}{N} \sum (Y_{pred,i} - Y_{act,i})^2 \quad (7)$$

213 where N is the number of samples, $Y_{pred,i}$ is the predicted data, and $Y_{act,i}$ is the actual data. The model development work was
 214 carried out by employing both the input and output parameters from the in-situ sources. It enables the ANN models to
 215 implement the input data of any remote sensing sources to produce OHC estimates subject to the reliability and accuracy of
 216 those data sources. The particle swarm optimization technique (Kennedy and Eberhart, 1995; Shi and Eberhart, 1998) was
 217 employed for hyperparameter tuning, and the hyperparameters' combinations corresponding to each modelling depth are
 218 presented in Table 1. The Joblib module of Scikit-Learn library was used to save all the TSL and OHC models of various
 219 depths considered in this study, and the same module was used to load the TSL and OHC models of desired depth with the
 220 help of a unified Python script.

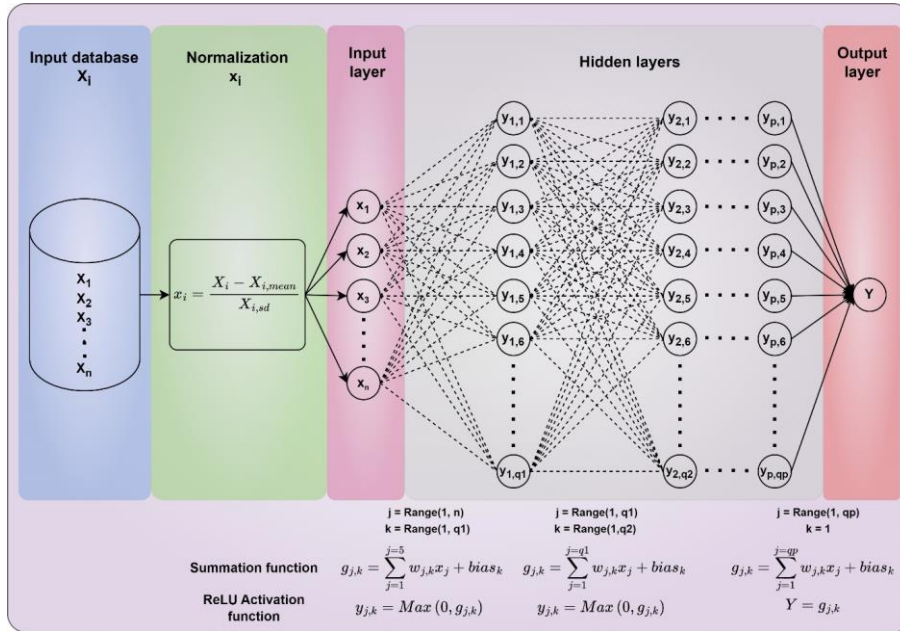

221
 222 **Figure 3.** Schematic of the ANN architecture employed in the modelling of TSL and OHC parameters. The flow of the
 223 modelling and the associated mathematical transformations/formulations are given by considering a typical ANN architecture
 224 with n input parameters, one output parameter, p hidden layers, and $q1$ to qp neurons in each hidden layer.

235

236 **Figure 3.** Schematic of the ANN architecture employed in the modelling of TSL and OHC parameters. The flow of the
 237 modelling and the associated mathematical transformations/formulations are given by considering a typical ANN architecture
 238 with n input parameters, one output parameter, p hidden layers, and $q1$ to qp neurons in each hidden layer.

239 **4. Results and discussion**

240 The performance of TSL and OHC models on **unseen** data from the in-situ and satellite sources was assessed using density
 241 scattergrams and statistical metrics. These metrics include mean bias error (MBE), mean bias percentage error (MBPE), mean
 242 absolute error (MAE), mean absolute percentage error (MAPE), root mean square error (RMSE), Pearson correlation
 243 coefficient (R), slope, and intercept (also referred and presented in Prakash and Shanmugam, 2022). To better understand the

Formatted: Highlight

244 model performance, mean values of in-situ data were computed for the validation period and used to compute the weighted
245 average of validation metrics across all the depth extents.

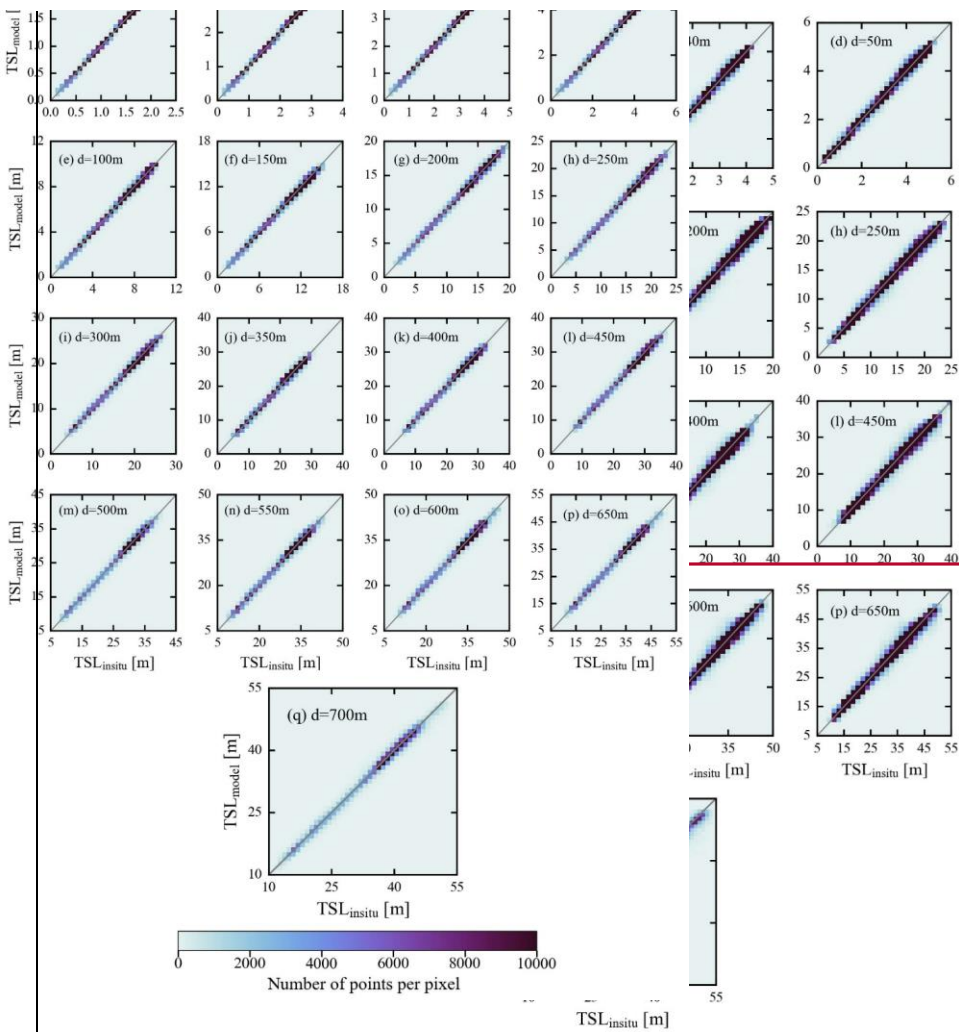

246 **4.1 In-situ validations with unseen data. Validation with independent in-situ data**

247 The main objective of the **in-situ-based validation with unseen data independent validation using in-situ data** is to evaluate the
248 generalization ability and overall accuracy of TSL and OHC-ANN models on unseen data. For this purpose, the in-situ
249 measured variables such as SST, SSS, and latitude / longitude were inputted into these models to output the predicted values
250 which were then compared with in-situ TSL and OHC data. The number of **independent-validation (unseen)** data points and
251 their spatial distribution are presented in Table 2 and Fig. A1(b). **The validation density scattergrams showed high correlation**
252 **and low errors with the model-predicted values (Figs. 4 and 5). The results in the form of density scattergrams are shown in**
253 **unseen data of all the depth extents without any overfitting (Table 2 and Fig. 4). From Table 2 and Fig. 4, the performance of**
254 observed in the case of OHC estimates as it primarily depends on the TSL estimates (Table 2 and Fig. 5). The high values of
255 R indicate a strong positive correlation between the predicted and in-situ OHC (TSL) values. This suggests that the models are
256 generally capable of capturing OHC (TSL) patterns in the data. The slope and intercept of the regression line between predicted
257 and actual values are close to 1 and 0, respectively. This suggests that the model-predicted values have good agreement with
258 the actual values with a minimal bias. The RMSE values are notably small implying that the predicted OHC values have a
259 little random error when compared to the actual data. The MBE and MBPE values are close to zero, indicating that the model-
260 predicted values have a negligible systematic error when compared to the actual values. The low MAE and MAPE values are
261 also indicating a high accuracy with the model-predicted OHC values. These results clearly demonstrate that the proposed
262 ANN models succeeded in generalizing and accurately predicting the measured OHC (TSL) data with a high accuracy.

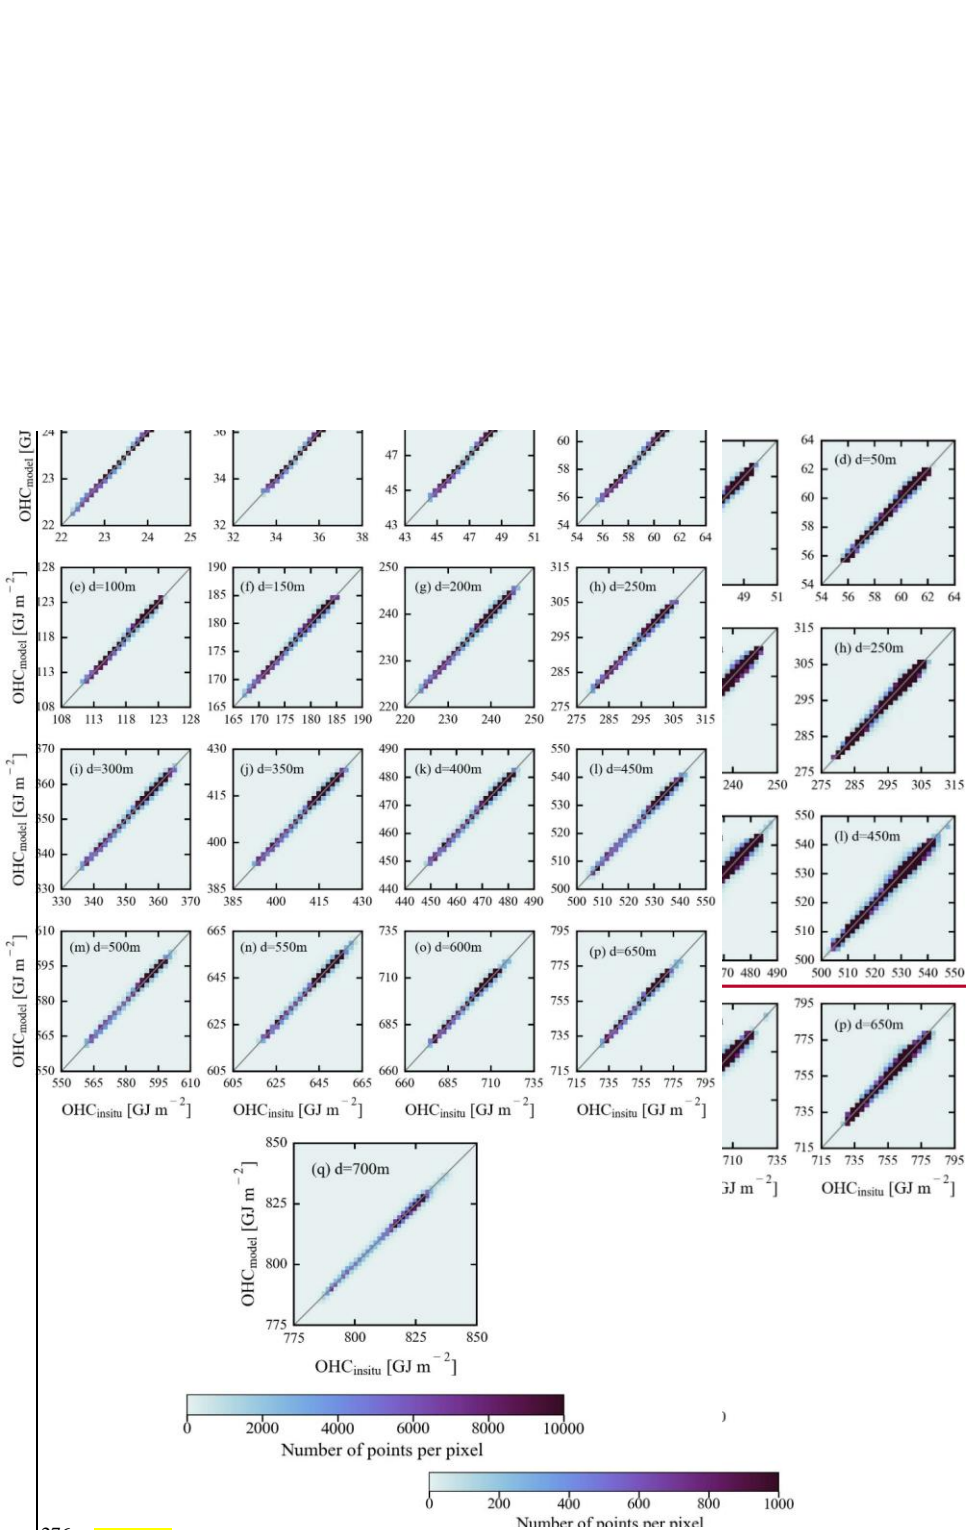

263 Spatial distribution of mean percentage error (MPE) over the global open oceanic region was computed by averaging
264 the observed percentage errors of all modelling depths available at each pixel (Fig. A2) for estimating the OHC changes. It is
265 observed that the models' performance is comparatively low over the north-western parts of the North Atlantic gyre,
266 southwestern parts of the South Atlantic gyre, Kuroshio extension, and Antarctic circumpolar regions **due to the high eddy**
267 **kinetic energy (Beech et al., 2022; Ni et al., 2023).** An elaborate note on the potential sources of the observed MPE values is
268 given in Sect. 4.4. Further, the entire validation dataset was divided into two parts in terms of the observed overestimation and
269 underestimation of data. In the cases of overestimation (underestimation), 95% of the data points have a MPE of less than or
270 equal to 0.47% (0.44%). The lower values of MPE indicate that the proposed ANN models succeed in capturing the OHC
271 patterns in all major oceanic basins and can be used to produce accurate OHC products based on their implementation on real-
272 time data.

284 4.2. ~~Satellite validations with unseen data~~ **Satellite-based independent validation**

285 The performance of the proposed ANN models in satellite-based applications has been assessed by injecting daily SST and
286 SSS data from the satellite sources (refer to Sect. 2.2) in place of the in-situ sources. The choice of satellite sources for SST
287 and SSS data is completely subjective to the intended application and their compatibility in terms of spatial and temporal
288 resolutions, whereas geographical coordinates data can be employed from WOA corresponding to the climatological TSL and
289 OHC data. It is recommended to resample SST and SSS data to the WOA grid to eliminate the discrepancies arising from the
290 non-uniform spatial references among the input data. ~~The satellite-based SST, ORA-based SSS, latitude, and longitude data
291 were then given as the inputs to the ANN models for producing TSL and OHC estimates of all the depth extents considered in
292 this study. In the current study, the NOAA Advanced Very High Resolution Radiometer (AVHRR) Optimum Interpolation
293 Sea Surface Temperature products (OISST v2.1) were used for daily SST data of 0.25° spatial resolution (Huang et al., 2021).
294 Daily SSS data of the same spatial resolution were obtained from the ORAS5 reanalysis system of the European Centre for
295 Medium Range Weather Forecasts at the CMEMS portal (Product ID: GLOBAL_REANALYSIS_PHY_001_031) (Zuo et al.,
296 2017). The NetCDF4 and NumPy Python libraries were used to read and resample satellite data to the WOA 18 grid, and to
297 collocate with the corresponding Argo in-situ data points. The accuracy of the satellite-based SST and SSS was verified by
298 Argo measured SST and SSS profile data (N = 244722). The observed R, RMSE, MBE, and MAE values in SST & SSS
299 validations are 0.99 & 0.99, 0.51°C & 0.26 PSU, 0.05°C & 0.006 PSU, and 0.33°C & 0.12 PSU, respectively. High
300 correlation coefficients and low errors indicate the minimal deviation of satellite-based data from actual (in-situ) data and
301 ensure the reliability of satellite data in accurately representing the physical oceanographic conditions. The satellite-based
302 SST, SSS, latitude, and longitude data were then given as the inputs to the ANN models for producing TSL and OHC estimates
303 of all the depth extents considered in this study. Consequently, the model-derived TSL and OHC estimates were compared
304 with Argo-measured in-situ data, and the satellite-based independent-validation results are presented in this section (Table 3
305 and Figs. 6 and 7).~~

306 The performance of the proposed ANN models on satellite-based independent-validation data (Table 3, Figs. 6 and
307 7) is rather similar to their performance on in-situ-based independent-validation data (Table 2, Figs. 4 and 5). However, the
308 models' performance on satellite-based independent-validation data was marginally low as compared to the in-situ-based
309 validation data, likely due to the errors associated with the satellite-derived products. According to the statistical results, the R
310 values were observed to be slightly lower by an average percentage decrease of 0.11% across all depth extents. Similarly, the
311 RMSE, MBE, MBPE, MAE, and MAPE were slightly larger than those values observed during the in-situ-based independent
312 validation datasets. This relatively lower performance of the proposed models on the satellite-based independent-validation
313 datasets can be observed by comparing the spatial maps and the distribution of MPE (Figs. A2 and A3). The relatively higher
314 magnitudes of MPE can be observed over the northwestern parts of the North Atlantic gyre, southwestern parts of the South
315 Atlantic gyre, Kuroshio extension, and Antarctic circumpolar regions based on in-situ-based validation data. And, 95% of the
316 data have a MPE of less than or equal to 0.56% (0.5%) in the cases of overestimation (underestimation), which is higher than

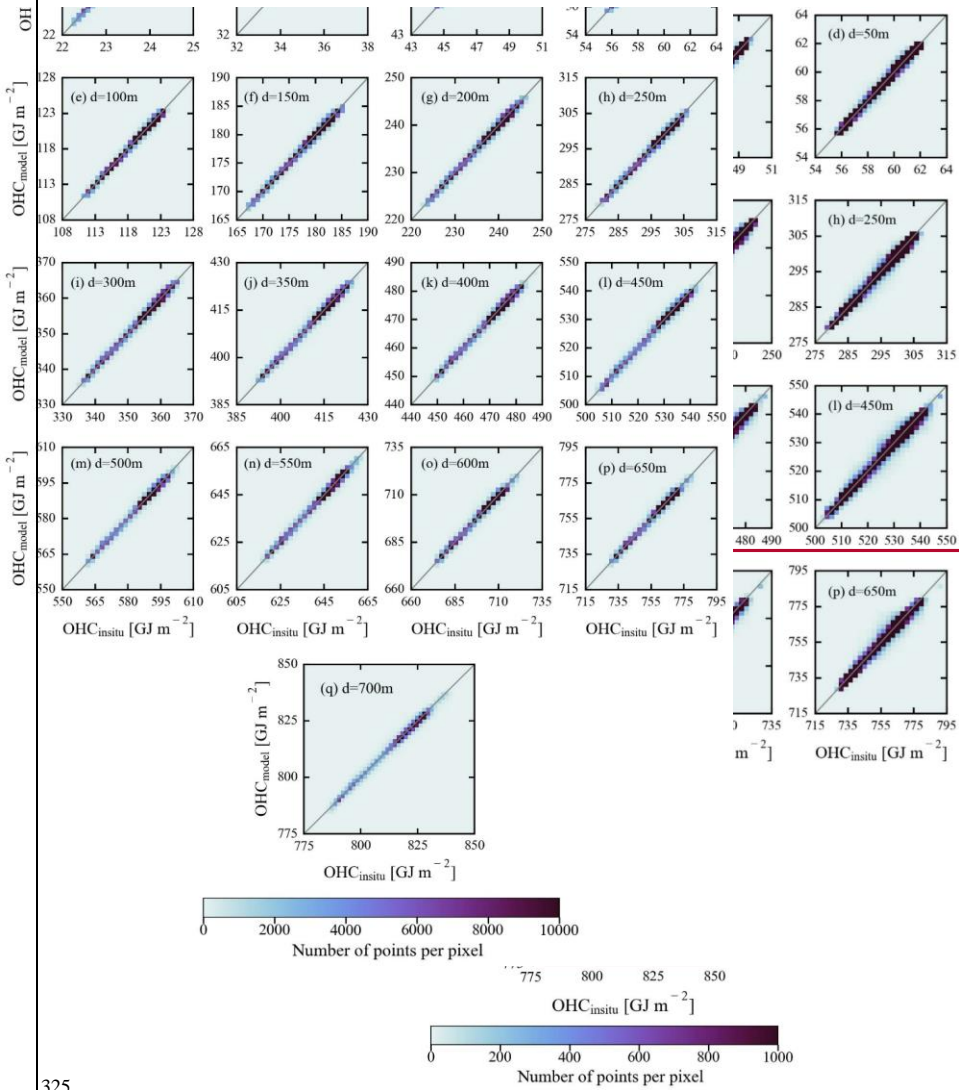

317 those reported in Sect. 4.1. Though the performance of the proposed models' on satellite-based data is comparatively lower
 318 than the in-situ-based validation data, the observed difference in various validation metrics is rather insignificant. It
 319 substantiates the efficiency of the proposed models in estimating OHC from satellite data at various depth extents over the
 320 major oceanic basins. However, it should be noted that the validation results presented in this section are subject to vary with
 321 the other sources of satellite-based SST and SSS data.

322

332

333 **4.3. Comparison with the contemporary satellite-based OHC models**

334 Comparison of our ANN models with the existing models is crucial to determine the relative uncertainty in the OHC estimates.
 335 Previously, an ANN algorithm suite was developed by the National Remote Sensing Centre (NRSC) of ISRO to disseminate
 336 the daily OHC products over the North Indian Ocean (40°E-120°E, 0°-30°N) at a spatial resolution of 0.25 degree (Ali et al.,
 337 2012; Jagadeesh et al., 2015). This algorithm suite includes ANN models to estimate OHC at multiple depth extents such as
 338 50 m, 100 m, 150 m, 200 m, 300 m, 500 m, and 700 m for the given input data of sea level anomaly (SLA), SST, and OHC_{clim,d}.
 339 It estimates OHC changes by utilizing the satellite altimetry-based SLA data from AVISO (Archiving, Validation, and
 340 Interpretation of Satellite Oceanographic data) data portal, SST from the Advanced Microwave Scanning Radiometer-2
 341 (AMSR2) onboard JAXA's Global Change Observation Mission 1st-Water (GCOM-W1), and climatological OHC from the
 342 World Ocean Atlas-2009 monthly climatological CTD profiles. The multilayer perceptron regressor algorithm of neural
 343 networks with three hidden layers was used to estimate OHC of all seven depth extents. The number of data points used to
 344 develop and validate the NRSC-ANN algorithm were 11472 and 2479, respectively. To estimate OHC changes at different
 345 depths, this algorithm employs the Celsius scale, in-situ temperature, and average density data instead of the Kelvin scale,
 346 conservative temperature, and instantaneous density, respectively (see Eq. 3 in Jagadeesh et al., 2015).

347 For this inter-comparison purpose, validation datasets were prepared for the period of 2017-2020 by calculating in-
 348 situ OHC in both Kelvin and Celsius scales for the depth extents of 50 m, 100 m, 150 m, 200 m, 300 m, 500 m, and 700 m.
 349 Daily OHC data were obtained from the NRSC's Bhuvan portal and collocated with the corresponding Celsius-scaled in-situ
 350 OHC data to evaluate the NRSC-ANN model products. Similarly, satellite-based SST and **ORA-based** SSS data, and
 351 climatological TSL and OHC data were extracted by collocating with Kelvin-scaled in-situ OHC data for our ANN model to
 352 generate the OHC products. Evaluation of these two OHC products was done separately by means of the normalized metrics
 353 such as R, MBPE, and MAPE (Table 4).

354 **Table 4.** Statistical results for our ANN model and NRSC-ANN model obtained from another **independent-unseen** dataset of
 355 extents used in this study.

Depth (m)	N	R		MBPE (%)		MAPE (%)	
		NRSC-ANN model	Proposed ANN model	NRSC-ANN model	Proposed ANN model	NRSC-ANN model	Proposed ANN model
50	15595	0.9223	0.9303	-0.0012	0.0227	1.4762	0.1104
100	14546	0.8575	0.8780	-0.3539	0.0303	2.5145	0.1732

356

357

358 As expected, our ANN model gave more accurate OHC estimates for all depth extents and hence yielded higher
359 correlation coefficients and lower errors as compared to the NRSC-ANN model. The accuracy of OHC estimates produced by
360 our ANN model also increased with depth in contrast to that of NRSC-ANN OHC estimates. Our ANN model was
361 accomplished with the selection of key input parameters based on a precise theoretical basis, accurate computation of in-situ
362 parameters, and selection of separate ANN architectures.

363 It should be mentioned that SLA is the combined outcome of temperature (thermosteric), salinity (halosteric), and
364 water mass changes in the oceanic water column. The direct use of satellite altimeter-derived SLA without eliminating
365 halosteric and water mass change components results in weaker correlations with OHC of various depth extents. Moreover,
366 the different time spans were used in the computation of the mean sea level at AVISO (1993-2012) and monthly climatology
367 data at WOA09 (1955-2006). The pair of merged SLA data from AVISO/CMEMS and climatological OHC data from WOA
368 could lead to discrepancies in OHC estimates. Hence, the prime criterion followed in choosing the input parameters in the
369 current study is the theoretical relationship between the input and output parameters rather than the direct usage of all the
370 relevant parameters. The one-to-one relationship between OHC and TSL is employed in the OHC modeling. To arrive at TSL,
371 the theoretical dependency of TSL on temperature and salinity is considered in TSL modeling work. However, SLA and
372 climatological OHC data of the same base period are desirable and can be used in OHC (TSL) modeling if available in the
373 future. Under these considerations, the present study was focused on TSL modelling rather than the Alt GRACE approach
374 (Meysignae et al., 2019) to implement the ocean thermal expansion method to estimate OHC changes.

375 Celsius scale can be used to compute in-situ OHC where the temperature gradient is always on the positive side. The
376 usage of the Celsius scale when the temperatures are less than zero and greater than the seawater freezing point is not
377 appropriate because of the potential negative values. In addition, the conservative temperature is an accurate variable compared
378 to the direct in-situ temperature or potential temperature. It represents the actual heat content of a mixture of two water masses
379 which are characterized by variations of salinity, pressure, and temperature (Pawlowicz, 2013). Thus, the conservative
380 temperature is defined in absolute scale (Kelvin scale) and used to calculate the in-situ OHC. On the other hand, employing
381 instantaneous density rather than average density is essential to account for the variations in seawater density which is
382 determined by temperature and salinity changes.

383 The vertical distribution of conservative temperature varies from equatorial to polar regions, and it follows a non-
384 linear profile with a mixed layer at the top, a thermocline at the middle, and a deep ocean layer at the bottom. This suggests
385 that it is appropriate to customize the ANN hyperparameters for each modelling depth. In this study, hyperparameter tuning
386 was performed for each modelling depth and it resulted in a better understanding of OHC patterns at various depth extents.
387 Though a clear improvement was achieved with the proposed OHC models, a relatively lower correlation was observed for
388 our ANN models in the depth range of 100-300 m over the North Indian Ocean (refer to Table 4). Similar results were obtained
389 for the NRSC-ANN models as well. It implies that the proposed ANN models less generalized the OHC patterns at the
390 intermediate depths over the North Indian Ocean. The underlying factors for the less generalized OHC patterns are described

391 in the following section. Nevertheless, the results demonstrated that the proposed ANN models contributed to improving the
392 accuracy and quality of OHC products through the ocean thermal expansion method.

393 4.4. Potential sources of uncertainty in OHC estimates

394 The relationship between the surficial parameters (SST and SSS) and depth-integrated parameters (TSL and OHC) is the prime
395 factor for determining the efficiency of the proposed OHC models of various depth extents (Klemas and Yan, 2014). This
396 relationship is mainly influenced by a wide range of geophysical processes including ocean currents, vertical mixing
397 (upwelling/downwelling), stratification, fronts, gyres, eddies, and air-sea interface processes. In addition, different climate
398 modes and oscillations, solar radiation, sea ice, phytoplankton growth, freshwater inputs, and winds can also be considered in
399 this context. Monthly climatological CTD profiles obtained from the WOA-18 database were objectively analyzed to calculate
400 the mean SST and SSS fields over a period of 1955-2017. Hence, these climatological data along with real-time SST and SSS
401 data enabled the ANN models to better generalize the prevailing geophysical processes and subsequent patterns in TSL &
402 OHC of various depth extents. The same can be perceived from the improved accuracy levels observed during the **independent**
403 **validations carried out on unseen data (refer to Sects. 4.1 and 4.2) and the comparison with NRSC-OHC model products (Sect.**
404 **4.3).**

405 It should be noted that the established relationship between the input parameters (surficial and climatological) and
406 output parameters (TSL & OHC patterns) may not hold great in the events of the above complex geophysical processes where
407 the physical oceanographic conditions differ significantly from the prevailing conditions. Moreover, the relative contributions
408 of these geophysical processes are subject to vary depending on the time and location of the water parcel in oceans. Slightly
409 lower accuracy of the proposed ANN models can be attributed to the influence of these complex geophysical processes. The
410 in-situ and satellite-based retrieval of all these atmospheric/surface/subsurface processes and their incorporation into the ANN
411 models is difficult because of the scarcity/sparsity of the required datasets in different spatial, temporal, and vertical scales.
412 The above factors constitute a potential source of uncertainty in OHC estimates and reduce the generalization ability of the
413 model. **Hence, it is advisable to carry out vicarious calibration with the help of contemporary in-situ CTD profiles before**
414 **adopting the OHC estimates for further scientific analyses of specific interest in both regional and global scales.** Further efforts
415 are needed to better understand, quantify, and eliminate the different sources of observed uncertainties caused by the complex
416 geophysical oceanic processes. More number of in-situ CTD profiles are required to be collected and analyzed in such oceanic
417 regions to address the associated complex patterns and processes. **Future releases of WOA will certainly resolve the complex**
418 **patterns in OHC data with the inclusion of newly collected CTD profiles over various oceanic basins.**

419 5. Spatiotemporal variability of OHC

420 **Here, we present the long-term variability of model-derived OHC and its comparison with the existing global OHC products**
421 **for the period 1993-2020. The time period (1993-2020) was chosen based on the availability of satellite-based input data to**
422 **generate the model-derived OHC estimates and the existing OHC products considered. Thus, model-derived annual OHC**

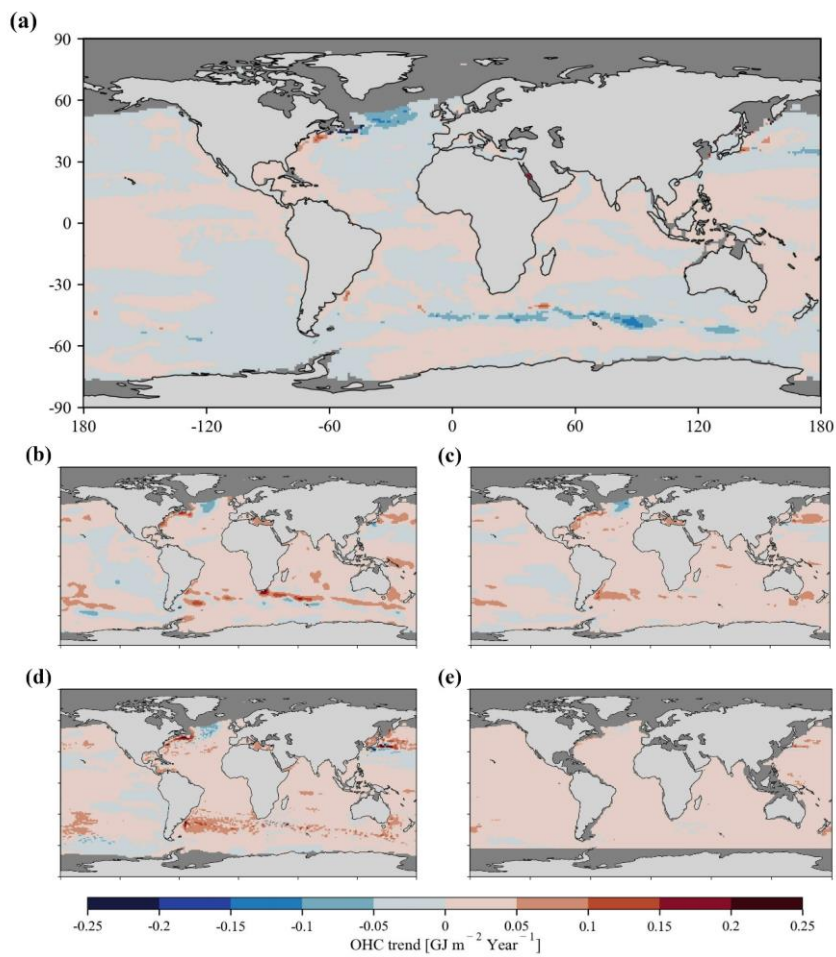

423 estimates were generated from 1993 to 2020 and computed annual time series of model-derived OHC anomalies (OHCA) with
424 reference to the 1993-2020 long-term mean. It is worth mentioning that the model-derived heat content estimates presented in
425 this section represent OHC changes in both shallower and deep oceanic basins of bathymetry levels ≥ 20 m. The bathymetry
426 values of each pixel were rounded off to the nearest and lowest modeling depth (d) with the help of GEBCO-2020 bathymetry
427 data, and the corresponding OHC_d values were considered for that pixel (GEBCO Compilation Group, 2020).

428 On the other hand, OHCA time series annual maps obtained from various global OHC products such as the National
429 Centers for Environmental Information (NCEI), Institute of Atmospheric Physics (IAP), Pacific Marine Environmental
430 Laboratory (PMEL), and OPEN-LSTM have been employed for comparison. NCEI employs the Objective analysis method
431 on in-situ CTD profile data of World Ocean Database-2009 and estimates annual OHCA at a spatial resolution of 1° with
432 reference to the 1955-2006 long-term mean (Levitus et al., 2012). Similarly, IAP employs the ensemble optimal interpolation
433 with a dynamic ensemble approach on in-situ CTD profile data of World Ocean Database-2013 and distributes monthly OHC
434 estimates at a spatial resolution of 1° (Cheng et al., 2017). Annual OHC means were computed from IAP monthly OHC data,
435 and annual OHCA estimates were generated with reference to the 1993-2020 long-term mean. Recently, PMEL has developed
436 a random forest regression model to predict OHCA of 0-40 m, 40-90 m, 90-190 m, 190-290 m, 290-450 m, 450-700 m, 700-
437 950 m, 950-1450 m, etc with reference to the 1993-2022 long-term mean. This PMEL random forest regression model employs
438 satellite-based SST, SSH (SLA), latitude, longitude, and time data to predict weekly OHCA estimates at a spatial resolution
439 of 0.25° (Lyman and Johnson, 2023). In the current study, PMEL layer-wise OHCA estimates from surface to 700 m have
440 been summed up at each pixel to arrive at weekly OHCA spatial maps, and subsequently computed corresponding annual
441 OHCA estimates. Similarly, Su et al., (2021) have developed a long short-term memory neural network method to produce
442 monthly OHC estimates (OPEN-LSTM) at a spatial resolution of 1° . OPEN-LSTM employs satellite-based SSH (SLA), SST,
443 zonal and meridional components of sea surface wind, latitude, longitude, and day of the year to predict monthly OHC. Annual
444 OHC means were computed from OPEN-LSTM monthly OHC data, and annual OHCA estimates were generated with
445 reference to the 1993-2020 long-term mean.

446 Model-derived annual OHCA estimates were regridded to 1° spatial resolution to maintain uniform spatial reference
447 among all the OHC products considered. As the proposed models are built for open oceanic regions, the regions covered by
448 sea ice are masked in both the north and south poles by verifying the corresponding sea ice concentration data obtained from
449 the National Snow and Ice Data Center (Meier et al., 2021). Subsequently, long-term variability maps (Fig. 8) and time series
450 plots (Fig. 9) were produced to compare model-derived OHC estimates with the existing global OHC products. Further, the
451 information on percentage variance explained (PVE) by the observed long-term trend values is provided to realise the short-
452 term trends or periodic signals in OHC variability (Fig. A4). Higher PVE values indicate the persistent increase or decrease in
453 OHC throughout the study period, and vice versa.

454 Lower magnitudes of long-term warming/cooling trends (± 0.05 GJ m^{-2} Year $^{-1}$) are observed throughout the global
455 ocean (Fig. 8a). The corresponding PVE values are observed to be very low ($\leq 30\%$) which infer the intermittent trends in
456 majority of the global ocean rather than persistent warming/cooling (Fig. A4a). The same can be observed from the non-linear

457 distribution of OHCA time series indicating short-term periods of alternate warming and cooling during the study period (Fig.
458 9). However, the oceanic regions linked with Kuroshio current, Gulf stream, Antarctic circumpolar current, North Atlantic
459 cold blob, southeastern Pacific are experiencing relatively higher magnitudes of persistent warming/cooling (± 0.1 to 0.15 GJ
460 $\text{m}^{-2} \text{Year}^{-1}$, PVE 50-90%).

461

462 **Figure 8.** Spatial maps showing the long-term trends of OHC obtained from (a) the current model, (b) NCEI, (c) IAP, (d)
 463 PMEL, and (e) OPEN-LSTM products. Note that the oceanic regions shallower than 20 m depth and/or covered with sea ice
 464 are masked with a dark gray color.

465
 466 The spatial patterns of OHCA trends observed from NCEI (Fig. 8b), IAP (Fig. 8c), and PMEL (Fig. 8d) products are
 467 almost similar and relatively more warming regions compared to the model-derived OHC estimates (Fig. 8a). Similarly, the
 468 spatial distribution of corresponding PVE values is also same in NCEI, IAP, and PMEL products with higher values over vast
 469 oceanic regions of the Atlantic, Indian, and southeastern Pacific Oceans (Figs. A4b-A4d). NCEI, IAP, and PMEL products
 470 indicating persistent warming conditions over the vast oceanic regions of the Pacific, Atlantic, and Indian Oceans. The same
 471 can be observed from the persistent long-term warming throughout the study period (Fig. 9). On the other hand, OPEN-LSTM
 472 OHC estimates indicating lower warming patterns all over the globe except the North Atlantic cold blob and some parts of the
 473 Antarctic circumpolar current (Fig. 8e) with higher PVE values over vast oceanic regions of Pacific, Atlantic, and Indian
 474 Oceans (Fig. A4e). As a result, persistent long-term warming has been observed throughout the study period (Fig. 9).

475
 476 **Figure 9.** Time series distribution of global mean OHCA obtained from the current model and the existing OHC products
 477 observed over the period 1993-2020. Note that the NCEI time series has been shifted by subtracting 0.3 GJ m^{-2} to better
 478 compare with the remaining OHC time series plots.

479 The observed time series plots have indicated contrasting trends between the current OHC model and the existing
 480 products. The observed time series plot of model-derived OHCA has indicated alternate periods of short-term cooling and
 481 warming during the current study period. Global open oceans have witnessed a cooling trend of $-0.017 \text{ GJ m}^{-2} \text{ Year}^{-1}$ (PVE
 482 76.99%) during 1993-1999, a warming trend of $+0.069 \text{ GJ m}^{-2} \text{ Year}^{-1}$ (PVE 92.73%) during 1999-2002, a cooling trend of
 483 $-0.054 \text{ GJ m}^{-2} \text{ Year}^{-1}$ (PVE 99.71%) during 2002-2008, and a warming trend of $+0.007 \text{ GJ m}^{-2} \text{ Year}^{-1}$ (PVE 36.50%) during
 484 2008-2020. The observed results indicate the efficiency of the current model by capturing the ocean cooling during 2003-2006
 485 (Loehle, 2009; Lyman et al., 2006) and the global warming hiatus during 1998-2013 (Trenberth, 2015). Whereas the observed

486 time series plots of NCEI, IAP, PMEL, and OPEN-LSTM products indicated persistent warming trends of $+0.017 \text{ GJ m}^{-2} \text{ Year}^{-1}$
487 $(\text{PVE } 95.75\%)$, $+0.019 \text{ GJ m}^{-2} \text{ Year}^{-1}$ $(\text{PVE } 97.94\%)$, $+0.0198 \text{ GJ m}^{-2} \text{ Year}^{-1}$ $(\text{PVE } 97.19\%)$, and $+0.0195 \text{ GJ m}^{-2} \text{ Year}^{-1}$ $(\text{PVE}$
488 $97.48\%)$, respectively. However, full-depth pan-global mean OHCA estimates by including OHC estimates over ice-covered
489 oceanic regions are required to substantiate these global ocean cooling and global warming hiatus signatures, and to realize
490 the role of excess heat added by anthropogenic climate change.

491 5. A preliminary analysis of global OHC data

492 Accurate reconstruction of OHC and analysis of its regional patterns and long-term global records are critical for estimating
493 the Earth Energy Imbalance and understanding the evolution of the climate change. Owing to the lack of instrumentation to
494 cover geographic and depth ranges, OHC estimates from the in-situ measured temperatures are temporally limited and
495 insufficiently widespread to capture its spatiotemporal changes and structures. OHC estimates from either different mapping
496 methods or Ocean reanalyses (ORAs) have yielded large uncertainties in past studies. Thus, improving OHC estimates through
497 a novel satellite-based method is the major step forward to overcome sparse observations and reduce the uncertainty in OHC
498 trends. In this study, we proposed an artificial network model to estimate OHC changes in global oceans. The proposed ANN
499 model incorporates the ocean thermal expansion method as a promising tool to estimate OHC changes from satellite data.
500 Accurate implementation of the ocean thermal expansion method was challenging due to the inability of the present-day
501 satellite systems to directly measure the ocean thermal expansion/contraction component. In this study, we proposed a satellite-
502 based novel approach to better implement the ocean thermal expansion method by establishing a relationship between the
503 surficial parameters such as SST & SSS and subsurface T-S profiles. This model predicts the depth-integrated TSL component
504 by making use of SST & SSS data and then utilizes the predicted TSL to estimate OHC changes. For this application, we
505 developed ANN models for TSL and OHC of various depth extents such as 20 m, 30 m, 40 m, 50 m, 100 m, 150 m, 200 m,
506 250 m, 300 m, 350 m, 400 m, 450 m, 500 m, 550 m, 600 m, 650 m, and 700 m. The performance of these TSL & OHC models
507 was assessed by using ~~in-situ-based data and satellite-based validation data, which were extracted from the unseen~~ in-situ-based
508 ~~independent data and satellite-based independent validation data, which were extracted from the unseen~~ in-situ CTD profiles
509 of the Argo program. Observed high correlations and low errors indicated that the proposed ANN models performed
510 exceptionally good on unseen data of all depth extents without any overfitting and can be used in conjunction with the sea ice
511 thermodynamics-based OHC model of the ice-covered oceanic regions (Prakash and Shanmugam, 2022) to better study the
512 ~~pan-global OHC changes by covering both open and ice-covered oceans of varying bathymetry levels ($\geq 20 \text{ m}$), trends and~~
513 ~~patterns in three dimensional distribution of OHC in the global oceans.~~

514 The model development and validation databases were prepared by using in-situ CTD profiles obtained from the Argo
515 program and collocated with the corresponding satellite-based daily data of SST (AVHRR v2.1) and SSS (ORAS5). The
516 multilayer perceptron regressor algorithm of deep neural networks was used and its architecture was optimized by evaluating
517 different combinations of hyperparameters for each modelling depth using the particle swarm optimization technique. Precise
518 consideration of theoretical aspects in the selection of input parameters, accurate computation of in-situ OHC, and customized

519 ANN architectures enabled the proposed models to establish the accurate relationships between the surficial parameters and
520 depth-integrated OHC (TSL) of various depths extents. The overall performance of the proposed models on satellite data was
521 good, suggesting that these models can be used for a variety of applications subjected to the accuracy requirements and can
522 produce accurate satellite-based OHC (TSL) estimates at various depth extents than previously possible. However, the
523 influence of complex geophysical processes on the generalization ability of ANN models is discussed, and realized that the
524 proposed models relatively less generalized the data in the events of complex geophysical processes. Further research should
525 focus on implementation of these models over the oceanic regions with complex geophysical processes. More number of in-
526 situ CTD profiles need to be collected and analyzed in such oceanic regions to address the associated complex patterns. ~~Future~~
527 ~~releases of WOA will certainly resolve the complex patterns in OHC data with the inclusion of newly collected CTD profiles~~
528 ~~over various oceanic basins.~~ However, the scope of the current research includes minimizing the observed marginal gap by
529 exploring new methods/parametrizations in satellite-based OHC modelling approaches.
