7 **Abstract.** Ocean heat content (OHC) is a depth-integrated physical oceanographic variable used to precisely measure ocean
8 warming. Because of the limitations associated with in-situ CTD data and Ocean Reanalysis system products, satellite-based
9 approaches have gained importance in estimating the daily to decadal variability of OHC over the vast oceanic region. Efforts
10 to minimize the biases in satellite-based OHC estimates are needed to realize the actual response of the ocean to the brunt of
11 climate change. In the current study, an attempt has been made to better implement the satellite-based ocean thermal expansion
12 method to estimate OHC at 17 depth extents ranging from the surface to 700m. To achieve this objective, an artificial neural
13 network (ANN) model was developed to derive thermosteric sea level (TSL) from a given dataset of sea surface temperature,
14 sea surface salinity, geographical coordinates, and climatological TSL. The model-derived TSL data were used to estimate
15 OHC changes based on the thermal expansion efficiency of heat. Statistical analysis showed high correlation coefficients and
16 low errors in satellite-derived TSL / OHC at 700 m water depth (N 388469, R 0.9926 / 0.9922, RMSE 1.16 m / 1.56 GJ m⁻²,
17 MBE -0.1917 m / -0.2400 GJ m⁻², MBPE -0.4560% / -0.0290%, MAE 0.763 m / 1.029 GJ m⁻², and MAPE 2.34% / 0.13%)
18 and nearly similar results at the remaining depth extents. These results suggest that the proposed ANN models are capable of
19 accurately estimating OHC changes on real-time data and three-dimensional distribution patterns of depth-integrated OHC
20 trends in the global ocean. In addition, the first-ever attempt to estimate the ocean thermal expansion component (*i.e.*, TSL)
21 from satellite data was successful and the model-derived TSL can be used to obtain high-end sea-level rise products in the
22 global ocean.

23 1. Introduction

24 Owing to the vast heat capacity and spatial coverage, the oceans balance the planet's temperatures by absorbing 93% of the
25 excess atmospheric heat caused by the greenhouse effect and global warming (Abraham et al., 2013; IPCC, 2014; Roemmich
26 et al., 2015; Riser et al., 2016; Trenberth et al., 2016; Meyssignac et al., 2019). A precise understanding of the depth-wise
27 penetration of this heat and its accumulation in the upper oceanic layers is inevitable (Liang et al., 2015; Baxter, 2016; IPCC,
28 2022). Ocean heat content (OHC), a depth-integrated physical oceanographic variable that refers to the amount of heat energy
29 accumulated between any two depths, has gained attention in various studies of the Earth Energy Imbalance (Von Schuckmann

30 et al., 2016; Trenberth et al., 2016; Cheng et al., 2017; Meyssignac et al., 2019; Cheng et al., 2022). Thus, accurate estimation
31 of OHC changes at various depth extents is vital and the motivation of the current study.

32 To obtain a complete picture of OHC changes at different depths, the direct measurements of in-situ conductivity,
33 temperature, and depth (CTD) profiles are necessary. These in situ measurements of the ocean properties are limited in terms
34 of depth and spatial coverages, leading to the biased global reconstruction of OHC estimates owing to the sparse measurement
35 data and spatial coverage deficiencies (Jagadeesh et al., 2015; Meyssignac et al., 2019; Marti et al., 2022). However, the in-
36 situ CTD profile measurements have been used to develop and validate the different OHC models (Momin et al., 2011;
37 Jagadeesh et al., 2015; Su et al., 2020; Prakash and Shanmugam, 2022). In addition, synthetic CTD profile data generated by
38 the Ocean Reanalysis systems (ORA) have been used to compute OHC variability in spatial and temporal scales (Balmaseda
39 et al., 2015; Palmer et al., 2017). More recently, satellite-based methods have become crucial to overcome the limitations in
40 the in-situ measurements of OHC changes, to ensure the OHC trend at a global scale, and to understanding the evolution of
41 the Earth's climate system (Meyssignac et al., 2019; Prakash and Shanmugam, 2022).

42 The existing satellite-based OHC algorithms can be broadly grouped into three approaches based on the employed
43 principles/parametrizations: (i) internal tide oceanic tomography (ITOT), (ii) ocean net surface heat fluxes, and (iii) ocean
44 thermal expansion. Apart from these approaches, research is exploring ways to make use of tidal magnetic satellite observations
45 (Irrgang et al., 2019), electrical conductance (Trossman and Tyler, 2019), and atmospheric oxygen & carbon dioxide
46 concentrations (Resplandy et al., 2018) to infer OHC changes. The ITOT technique involves correlating the satellite altimeter-
47 derived internal tide phase changes with ocean warming to estimate the OHC variability. This technique is still at the proof-
48 of-concept level and the associated challenges remain to be addressed (Zhao, 2016; Meyssignac et al., 2019). The OHC
49 estimation through the ocean net surface heat fluxes employs several assumptions and approximations in deriving the input
50 parameters to compute the radiative and turbulent heat fluxes, which in turn leads to a higher uncertainty of global OHC
51 changes (Wild et al., 2015; L'Ecuyer et al., 2015; Meyssignac et al., 2019). On the other hand, the ocean thermal expansion
52 method is a promising technique for the estimation of OHC by considering the thermosteric sea level (TSL) and expansion
53 efficiency of heat (EEH). Numerous satellite-based OHC models have been developed based on the sea surface height anomaly
54 data from altimeters, water mass change equivalent sea level anomaly data from the Gravity Recovery and Climate Experiment
55 mission (GRACE), sea surface temperature from the various radiometers onboard satellites, and wind speed/stress from
56 scatterometers/numerical weather models. Pioneering work done by White and Tai (1995), Chambers et al. (1997), Polito et
57 al. (2000), and Sato et al. (2000) have attempted to implement the ocean thermal expansion method based on a relationship
58 between OHC and satellite altimeter-based sea surface height anomaly (SSHA). It should be mentioned that regardless of the
59 source, the density of seawater changes when it is subjected to heating/cooling, and it eventually reflects in sea surface
60 topography. The SSHA data recorded by the satellite altimeters comprise the sea surface topography changes due to tides,
61 atmospheric pressure, salinity (haline), and barotropic flows along with the thermal effects. The SSHA changes due to the tides
62 and atmospheric pressure can be corrected, but the effects of salinity and barotropic flows remain unresolved with the OHC
63 estimates produced by Wang and Tai (1995) and Chambers et al. (1997). Sato et al. (2000) have introduced a haline correction

64 factor as the integral product of the haline contraction coefficient and salinity anomaly from in-situ CTD profile data. Owing
65 to the limitations associated with in-situ data, the in-situ-based haline correction cannot be applied to satellite altimeter-based
66 SSHa data while correlating with the space and time-varying OHC data. Jayne et al. (2003) have proposed the Alt-GRACE
67 approach to resolve the effect of barotropic flows in sea surface topography by subtracting the satellite gravimetry-derived
68 water mass change component from SSHa data. Though the Alt-GRACE approach has improved the accuracy of satellite-
69 based OHC estimates compared to Wang and Tai (1995), Chambers et al. (1997), Polito et al. (2000), and Sato et al. (2000),
70 the issues associated with the haline effects and other approximations on the ocean thermal expansion coefficient and seawater
71 density data have led to significant uncertainties in satellite-based OHC estimates. With the advancement of artificial
72 intelligence, several researchers have attempted to model OHC by directly relating it with the satellite-based parameters by
73 using deep-learning regression techniques (Jagadeesh and Ali, 2006; Momin et al., 2011; Chacko et al., 2015; Jagadeesh et al.,
74 2015; Su et al., 2020, 2021; Marti et al., 2022). These deep-learning models have oversimplified the OHC problem by
75 neglecting the effects of salinity and barotropic flows. In addition, no previous work have accounted for the space and time-
76 varying nature of the ocean thermal expansion coefficient and seawater density in OHC computations. The other common
77 drawbacks with the existing work are discussed in Sect. 4.3. Consequently, there is a need for developing a satellite-based
78 model to accurately implement the ocean thermal expansion method to estimate OHC by resolving all the issues associated
79 with salinity variation, barotropic flows, ocean thermal expansion, seawater density, choice of temperature and its units.

80 Given the above background, we have made a major attempt to develop and implement a satellite-based ocean thermal
81 expansion model for estimating OHC changes at various depth extents such as 20 m, 30 m, 40 m, 50 m, 100 m, 150 m, 200 m,
82 250 m, 300 m, 350 m, 400 m, 450 m, 500 m, 550 m, 600 m, 650 m, and 700 m. For this, artificial neural network (ANN)
83 architectures were developed to estimate TSL for the given sea surface temperature (SST), sea surface salinity (SSS),
84 geographical coordinates, and climatological TSL. The model-derived TSL estimates were then used to estimate OHC changes
85 by accounting the expansion efficiency of heat. The proposed models are capable of estimating TSL and OHC accurately at
86 multiple depth extents. The robustness of the new models was tested by comparison of satellite-derived TSL and OHC with
87 in-situ data.

88 **2. Data**

89 For this study, in-situ CTD profile data (collected by Argo floats) were obtained from the World Ocean Database-2018 of the
90 NOAA's National Centers for Environmental Information Data Archive for the period of 2005-2020 (Boyer et al., 2018a).
91 These data have been extensively used by the research community for various ocean applications (Levitus et al., 2009; Momin
92 et al., 2011; Levitus et al., 2012; Cheng et al., 2014; Roemmich et al., 2015; Jagadeesh et al., 2015; Su et al., 2020). The World
93 Ocean Database (WOD) comprises the oceanographic data of diverse biogeochemical parameters that have been collected by
94 various institutions, agencies, individual researchers, and data recovery initiatives. The quality-controlled CTD profile data
95 (*accepted_value* flag) of standard depth levels recommended by the International Association of Physical Oceanography

96 (1936) were considered in this study to compute the TSL_d and OHC_d parameters and to obtain the SST and SSS data. The
97 standard depth levels considered for deriving the TSL and OHC are given as 20 m, 30 m, 40 m, 50 m, 100 m, 150 m, 200 m,
98 250 m, 300 m, 350 m, 400 m, 450 m, 500 m, 550 m, 600 m, 650 m, and 700 m. The in-situ TSL_d and OHC_d parameters were
99 computed by applying the integration formula (Eqs. 1 & 2) on the CTD profile data of depth range from the ocean surface to
100 the respective standard depth (d) as well as the SST and SSS data corresponding to the ocean surface. Similarly, the
101 climatological parameters such as $TSL_{clim,d}$ and $OHC_{clim,d}$ were computed from the monthly climatological temperature and
102 salinity data of 41 vertical levels obtained from the World Ocean Atlas-2018 (WOA) (Boyer et al., 2018b). The theoretical
103 considerations of computing OHC change at a depth can be found in Prakash and Shanmugam (2022) (Prakash and
104 Shanmugam, 2022), which were adopted in this study. The Gibbs-SeaWater (GSW) Oceanographic Toolbox of TEOS-10
105 (IOC et al., 2010) was used to compute the in-situ-based parameters including

$$106 \quad OHC_d = \int_0^d \rho C_p \theta \, dz \quad (1)$$

$$107 \quad TSL_d = \int_0^d \alpha \theta \, dz \quad (2)$$

108 where OHC_d refers to the heat energy accumulated in an oceanic layer of depth range from the surface to a stipulated depth
109 (d) and is given in the units of joules per unit area ($J \, m^{-2}$). Similarly, TSL_d (in meters) refers to the thermosteric sea level
110 integrated from the surface to a stipulated depth (d). And, θ is the conservative temperature in K (derived from in-situ
111 temperature, absolute salinity, and pressure), ρ is the seawater density in $kg \, m^{-3}$ (derived from the conservative temperature,
112 absolute salinity, and pressure), C_p is the specific heat capacity ($= 3991.87 \, J \, kg^{-1} \, K^{-1}$), and α is the thermal expansion coefficient
113 in K^{-1} (derived from the conservative temperature, absolute salinity, and pressure).

114 Python programming was used to prepare the individual databases for all the standard depth levels by extracting CTD
115 profile data from the WOD and WOA NetCDF files with the help of NetCDF4, NumPy, Pandas, and GSW libraries. Each
116 database was divided into two datasets, one for the model development spanning from 2005-2016 and one for validating the
117 model spanning from 2017-2020, by ensuring a well distribution in spatiotemporal scales over the global open ocean. The
118 spatial distribution of data points used to model TSL_{700} and OHC_{700} is shown in Fig. A1. The in-situ CTD profiles of depth
119 coverage shallower than 700 m are also included in this process of deriving the TSL and OHC of other depth extents. Indeed,
120 the number of CTD profiles and their distribution in global oceans is higher than the CTD profile density as shown in Fig. A1.

121 3. Methodology

122 3.1. Theoretical formulations

123 Ocean thermal expansion is the best proxy to model the heat content accumulated in an oceanic layer. Unlike freshwater,
124 seawater expands when it warms and contracts when it cools for temperatures above its freezing point. The volumetric
125 expansion of seawater is non-isotropic in nature due to the differences in the degree of constraint in different directions. In a
126 vertical direction, atmospheric pressure exerts a normal force on the seawater parcel at the surface. The magnitude of this

127 normal/vertical force is less compared to the horizontal forces exerted by physical barriers such as continental boundaries and
 128 geographic features on the ocean floor. It allows the ocean thermal expansion of seawater in the vertical direction rather than
 129 the horizontal direction, as the seawater is less constrained in the vertical direction compared to the horizontal direction. The
 130 amount of change in seawater volume in response to the net warming/cooling depends on the absolute conservative temperature
 131 and ocean thermal expansion coefficient (Eq. 2). Following are the GSW functions (Eqs. 3-5) (IOC et al., 2010) involved in
 132 the calculation of TSL (Eq. 2) for the given set of measured temperature (T), practical salinity (SP), pressure (P), longitude
 133 (x), and latitude (y).

134 $Absolute\ salinity\ (SA) = gsw.SA_from_SP(SP, P, x, y)$ (3)

135 $\Theta = gsw.CT_from_T(SA, T, P)$ (4)

136 $\alpha = gsw.Alpha(SA, \Theta, P)$ (5)

137 Hence, an attempt has been made in this study to model TSL as a function of SST, SSS, and geographical coordinates. The
 138 existing correlations between the proposed input parameters and the targeted output parameter were explored by employing
 139 in-situ-based data used in the model development process (Fig. 1).

140
 141 **Figure 1.** Heatmap showing the Pearson correlation coefficients between the input parameters (*i.e.*, SST, SSS, and
 142 geographical coordinates) and the output parameter (TSL) of various depth extents.

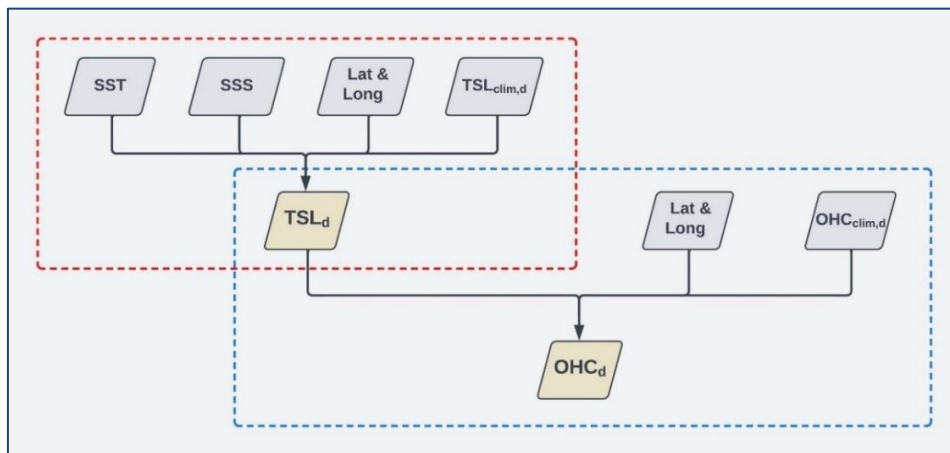

143 It is observed that SST has an almost one-to-one correlation with TSL at shallower depth extents, and can be solely
 144 used to model the thermal expansion of upper oceanic layers. Despite a decreasing trend in correlation strength when moving
 145 towards a deeper depth, SST plays a primary role in accounting for TSL variations at deeper depths, because of its strong
 146 correlations with TSL. Observed weaker correlations between SSS and TSL which are plausible owing to the salinity's
 147 secondary role in TSL variations as compared to the temperature variable. However, an increasing trend in correlation
 148 coefficients between SSS and TSL is observed towards the deeper depth extents. Hence, SST and SSS are complementary to
 149 each other in resolving the TSL variations, and their combination plays a major role in modelling TSL of all depth extents
 150 considered in this study. Apart from these physical parameters, absolute salinity used in the computation of seawater density,
 151 conservative temperature, and ocean thermal expansion coefficient is a function of geographical coordinates along with
 152 practical salinity and pressure (Eq. 3). By considering all these theoretical considerations and observed correlations, an attempt
 153 has been made to model TSL of various depth extents by employing SST, SSS, and geographical coordinates as the input

154 parameters along with the climatological TSL (Fig. 2). Here, TSL_d is an external manifestation of OHC_d stored in an oceanic
 155 layer based on EEH_d (Eq. 6). The model-derived TSL is further used to estimate OHC changes (as shown in Fig. 2 along with
 156 climatological OHC) as follows,

$$157 \quad OHC_d = \frac{TSL_d}{EEH_d} \quad (6)$$

158 where EEH is a conversion factor that explains the relationship between the relative changes in ocean heat content and the
 159 corresponding seawater thermal expansion. As it varies as a function of temperature, salinity, and pressure, EEH is not a
 160 constant value over the global ocean. Hence, ANN modelling is employed in this study to derive OHC from TSL by accounting
 161 the complex variations in EEH .

162
 163 **Figure 2.** Flow chart representing the parameters involved in TSL and OHC modelling. The red and blue dashed boxes
 164 represent the TSL and OHC frameworks employed in ANNs, respectively.

165
 166 **3.2. ANN model description**

167 This section explains the various steps and architectures involved in the ANN modelling of TSL and OHC. The multilayer
 168 perceptron regressor algorithm of deep neural networks was used to model both TSL and OHC (Pedregosa et al., 2011). It is
 169 observed that the input data of geophysical parameters are given in different units and scales. The range and order of SST,
 170 SSS, latitude, and longitude data are $-1.8\text{ }^{\circ}\text{C}$ to $34.15\text{ }^{\circ}\text{C}$ & $O(10^1)$, 2.53 PSU to 40.45 PSU & $O(10^1)$, -76° to 80° & $O(10^1)$,
 171 and -180° to 180° & $O(10^2)$, respectively. In addition, the range and order of $TSL_{clim,d}$ and $OHC_{clim,d}$ are also distinct and vary
 172 with water depth. Hence, the input data were normalized using the StandardScaler class of Scikit-Learn and feed-forwarded
 173 through the neural networks. This StandardScaler normalizes the raw data to ensure the mean and standard deviation of each
 174 input parameter as 0 and 1, respectively. It allows the ANN model to focus on the relative importance and relationships between
 175 the input parameters rather than their magnitude. The standardized input data were injected into the corresponding neurons in
 176 the input layer and forward propagated through the hidden layers and then the output layer by applying the random weights
 177 and rectified linear unit (ReLU) activation function at each neuron. The mathematical formulations and schematic

178 representation related to ANN architecture are shown in Fig. 3. The model outputs were compared with the actual data and
179 computed mean squared error (MSE) using a loss function (Eq. 7). In addition, L2 regularization (α_{L2}) was employed to add
180 a penalty term to the loss value to prevent overfitting. The observed error was then backpropagated through the network to
181 update weights and biases using the Adam optimizer based on the learning rate and gradient of the error (see Eq. 8 in Prakash
182 and Shanmugam, 2022). This process is repeated until the validation score improves more than 0.0001.

$$183 \quad MSE = \frac{1}{N} \sum (Y_{pred,i} - Y_{act,i})^2 \quad (7)$$

184 where N is the number of samples, $Y_{pred,i}$ is the predicted data, and $Y_{act,i}$ is the actual data. The model development work was
185 carried out by employing both the input and output parameters from the in-situ sources. It enables the ANN models to
186 implement the input data of any remote sensing sources to produce OHC estimates subject to the reliability and accuracy of
187 those data sources. The particle swarm optimization technique (Kennedy and Eberhart, 1995; Shi and Eberhart, 1998) was
188 employed for hyperparameter tuning, and the hyperparameters' combinations corresponding to each modelling depth are
189 presented in Table 1. The Joblib module of Scikit-Learn library was used to save all the TSL and OHC models of various
190 depths considered in this study, and the same module was used to load the TSL and OHC models of desired depth with the
191 help of a unified Python script.

214 **Figure 3.** Schematic of the ANN architecture employed in the modelling of TSL and OHC parameters. The flow of the
 215 modelling and the associated mathematical transformations/formulations are given by considering a typical ANN architecture
 216 with n input parameters, one output parameter, p hidden layers, and q_1 to q_p neurons in each hidden layer.

217 **4. Results and discussion**

218 The performance of TSL and OHC models on unseen data from the in-situ and satellite sources was assessed using density
 219 scattergrams and statistical metrics. These metrics include mean bias error (MBE), mean bias percentage error (MBPE), mean
 220 absolute error (MAE), mean absolute percentage error (MAPE), root mean square error (RMSE), Pearson correlation
 221 coefficient (R), slope, and intercept (also referred and presented in Prakash and Shanmugam, 2022). To better understand the
 222 model performance, mean values of in-situ data were computed for the validation period and used to compute the weighted
 223 average of validation metrics across all the depth extents.

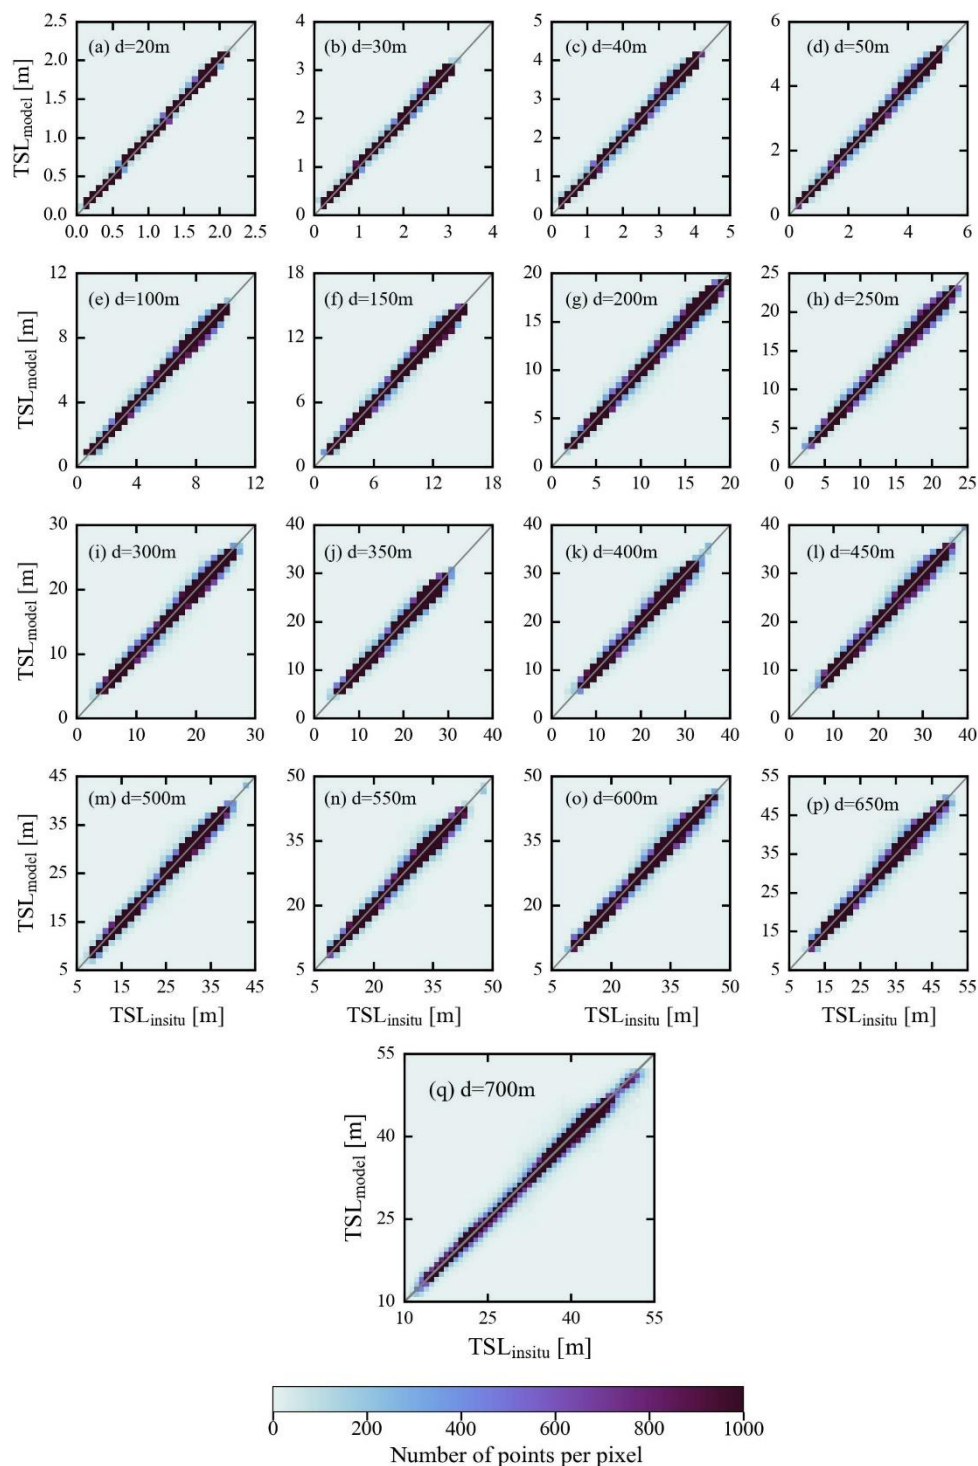

224 4.1. Validation with independent in-situ data

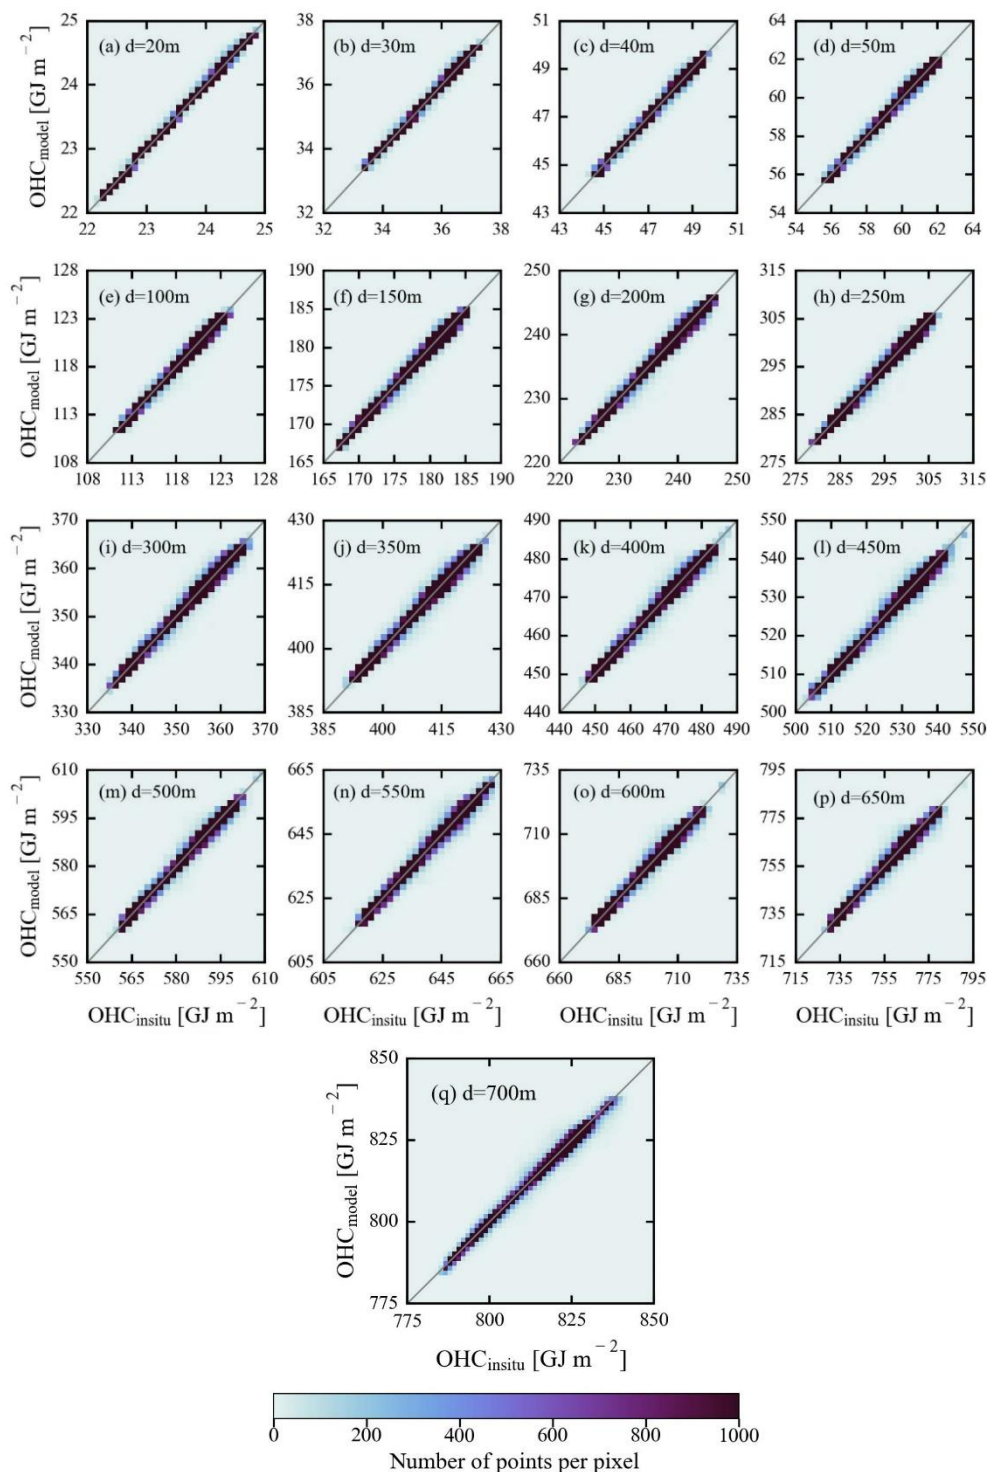

225 The main objective of the independent validation using in-situ data is to evaluate the generalization ability and overall accuracy
226 of TSL and OHC-ANN models on unseen data. For this purpose, the in-situ measured variables such as SST, SSS, and latitude
227 / longitude were inputted into these models to output the predicted values which were then compared with in-situ TSL and
228 OHC data. The number of independent validation data points and their spatial distribution are presented in Table 2 and Fig.
229 A1(b). The results in the form of density scattergrams are shown in Figs. 4 and 5. These results showed high correlation and
230 low errors with the model-predicted values. From Table 2 and Fig. 4, the performance of the TSL models is exceptionally
231 good on unseen data of all the depth extents without any overfitting. Similar model performance can also be observed in the
232 case of OHC estimates as it primarily depends on the TSL estimates (Table 2 and Fig. 5). The high values of R indicate a
233 strong positive correlation between the predicted and in-situ OHC (TSL) values. This suggests that the models are generally
234 capable of capturing OHC (TSL) patterns in the data. The slope and intercept of the regression line between predicted and
235 actual values are close to 1 and 0, respectively. This suggests that the model-predicted values have good agreement with the
236 actual values with a minimal bias. The RMSE values are notably small implying that the predicted OHC values have a little
237 random error when compared to the actual data. The MBE and MBPE values are close to zero, indicating that the model-
238 predicted values have a negligible systematic error when compared to the actual values. The low MAE and MAPE values are
239 also indicating a high accuracy with the model-predicted OHC values. These results clearly demonstrate that the proposed
240 ANN models succeeded in generalizing and accurately predicting the measured OHC (TSL) data with a high accuracy.

241 Spatial distribution of mean percentage error (MPE) over the global open oceanic region was computed by averaging
242 the observed percentage errors of all modelling depths available at each pixel (Fig. A2) for estimating the OHC changes. It is
243 observed that the models' performance is comparatively low over the north-western parts of the North Atlantic gyre,
244 southwestern parts of the South Atlantic gyre, Kuroshio extension, and Antarctic circumpolar regions. An elaborate note on
245 the potential sources of the observed MPE values is given in Sect. 4.4. Further, the entire validation dataset was divided into
246 two parts in terms of the observed overestimation and underestimation of data. In the cases of overestimation (underestimation),
247 95% of the data points have a MPE of less than or equal to 0.47% (0.44%). The lower values of MPE indicate that the proposed
248 ANN models succeed in capturing the OHC patterns in all major oceanic basins and can be used to produce accurate OHC
249 products based on their implementation on real-time data.

261

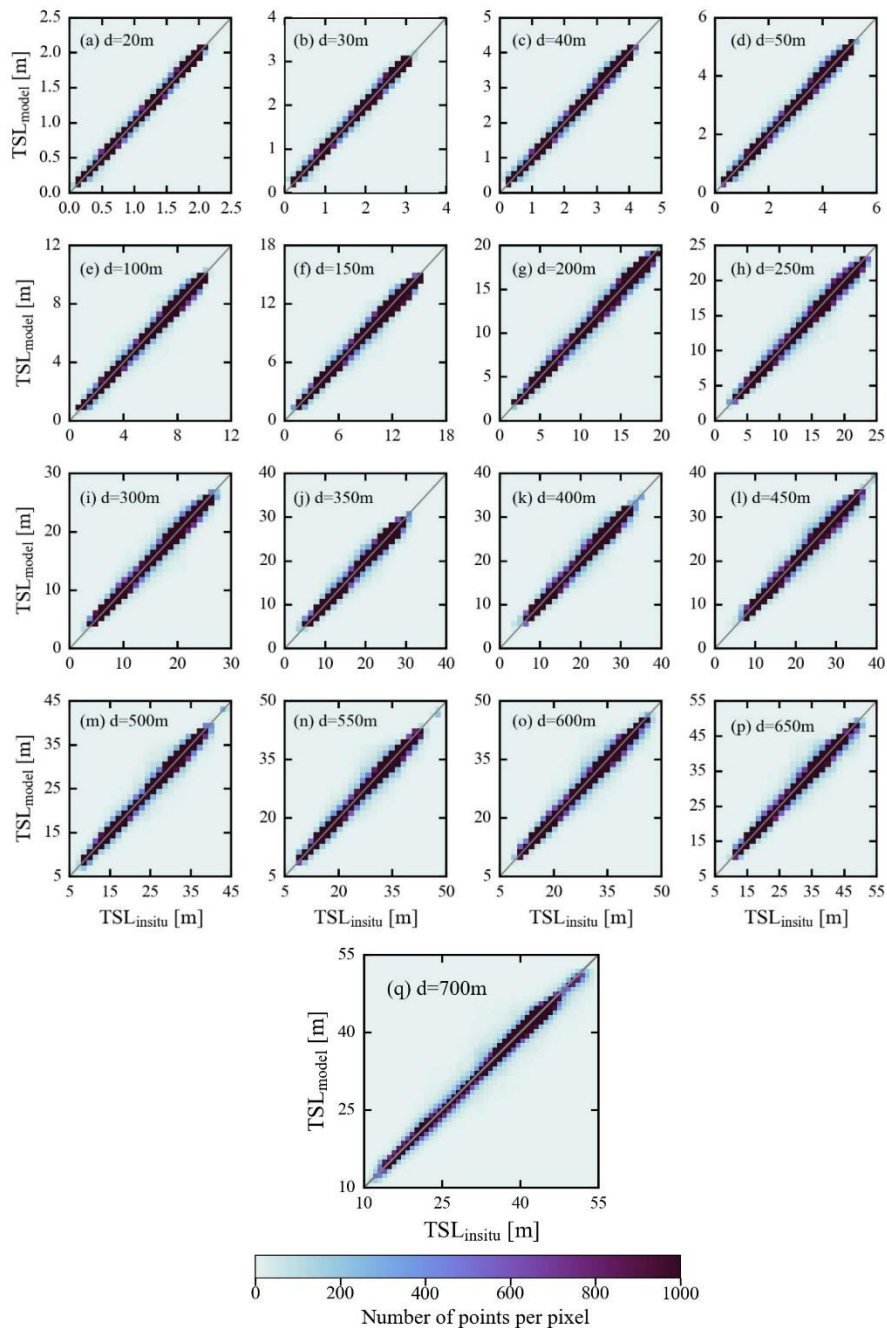

262 4.2. Satellite-based independent validation

263 The performance of the proposed ANN models in satellite-based applications has been assessed by injecting daily SST and
264 SSS data from the satellite sources in place of the in-situ sources. The choice of satellite sources for SST and SSS data is
265 completely subjective to the intended application and their compatibility in terms of spatial and temporal resolutions, whereas
266 geographical coordinates data can be employed from WOA corresponding to the climatological TSL and OHC data. It is
267 recommended to resample SST and SSS data to the WOA grid to eliminate the discrepancies arising from the non-uniform
268 spatial references among the input data. In the current study, the NOAA Advanced Very High-Resolution Radiometer
269 (AVHRR) Optimum Interpolation Sea Surface Temperature products (OISST v2.1) were used for daily SST data of 0.25°
270 spatial resolution (Huang et al., 2021). Daily SSS data of the same spatial resolution were obtained from the ORAS5 reanalysis
271 system of the European Centre for Medium-Range Weather Forecasts at the CMEMS portal (Product ID:
272 GLOBAL_REANALYSIS_PHY_001_031) (Zuo et al., 2017). The NetCDF4 and NumPy Python libraries were used to read
273 and resample satellite data to the WOA-18 grid, and to collocate with the corresponding Argo in-situ data points. The accuracy
274 of the satellite-based SST and SSS was verified by Argo-measured SST and SSS profile data ($N = 244722$). The observed R,
275 RMSE, MBE, and MAE values in SST & SSS validations are 0.99 & 0.99, 0.51°C & 0.26 PSU, -0.05°C & -0.006 PSU, and
276 0.33°C & 0.12 PSU, respectively. High correlation coefficients and low errors indicate the minimal deviation of satellite-based
277 data from actual (in-situ) data and ensure the reliability of satellite data in accurately representing the physical oceanographic
278 conditions. The satellite-based SST, SSS, latitude, and longitude data were then given as the inputs to the ANN models for
279 producing TSL and OHC estimates of all the depth extents considered in this study. Consequently, the model-derived TSL and
280 OHC estimates were compared with Argo-measured in-situ data, and the satellite-based independent validation results are
281 presented in this section (Table 3 and Figs. 6 and 7).

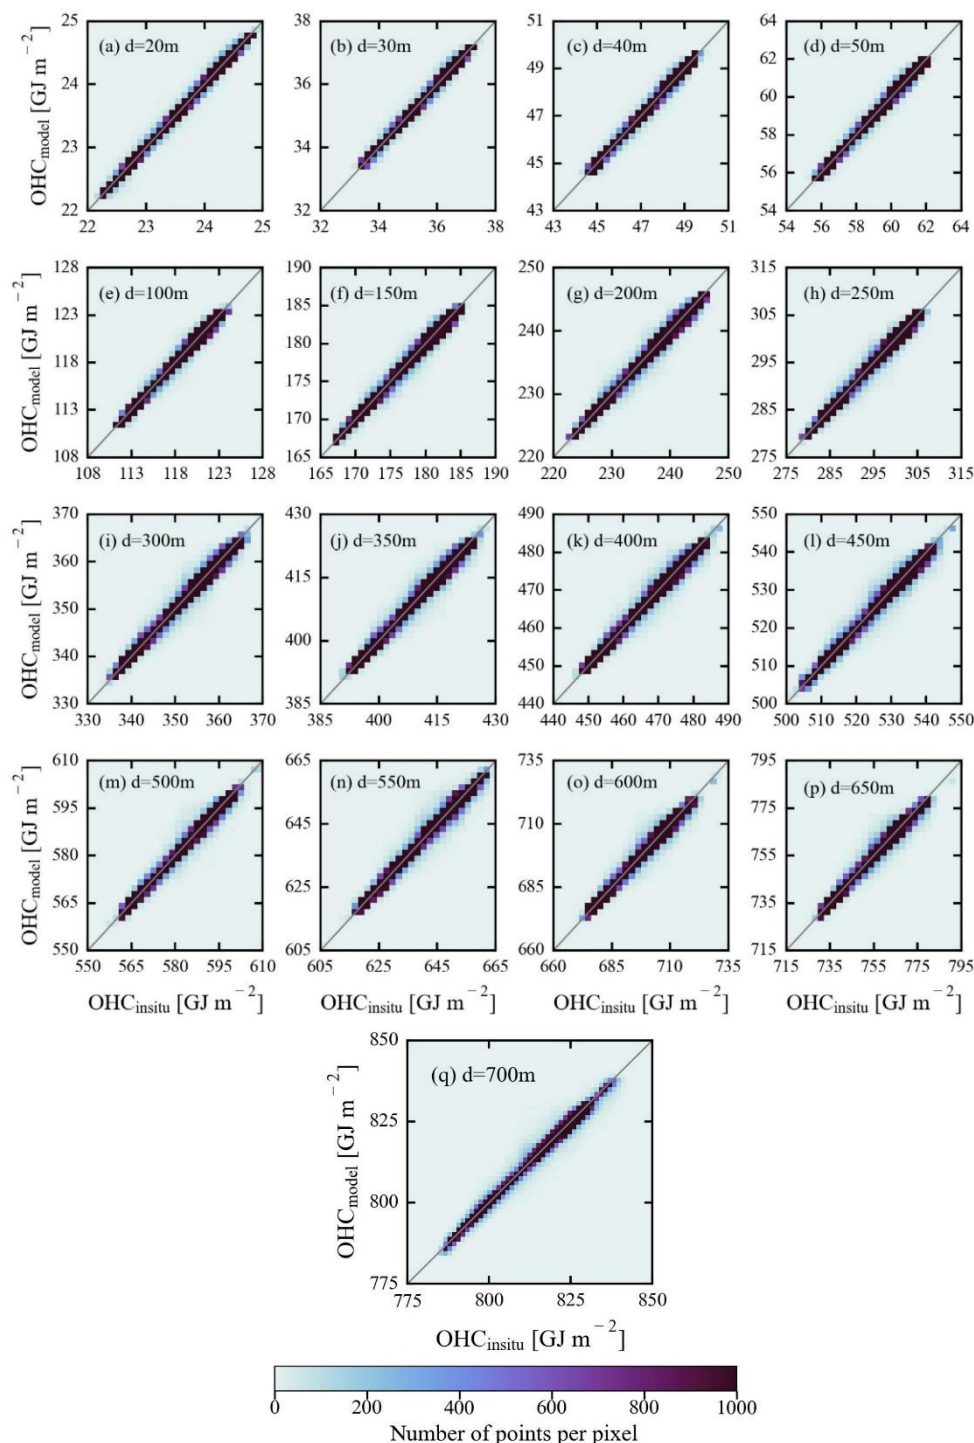

282 The performance of the proposed ANN models on satellite-based independent validation data (Table 3, Figs. 6 and
283 7) is rather similar to their performance on in-situ-based independent validation data (Table 2, Figs. 4 and 5). However, the
284 models' performance on satellite-based independent validation data was marginally low as compared to the in-situ-based
285 validation data, likely due to the errors associated with the satellite-derived products. According to the statistical results, the R
286 values were observed to be slightly lower by an average percentage decrease of 0.11% across all depth extents. Similarly, the
287 RMSE, MBE, MBPE, MAE, and MAPE were slightly larger than those values observed during the in-situ-based independent
288 validation datasets. This relatively lower performance of the proposed models on the satellite-based independent validation
289 datasets can be observed by comparing the spatial maps and the distribution of MPE (Figs. A2 and A3). The relatively higher
290 magnitudes of MPE can be observed over the northwestern parts of the North Atlantic gyre, southwestern parts of the South
291 Atlantic gyre, Kuroshio extension, and Antarctic circumpolar regions based on in-situ-based validation data. And, 95% of the
292 data have a MPE of less than or equal to 0.56% (0.5%) in the cases of overestimation (underestimation), which is higher than
293 those reported in Sect. 4.1. Though the performance of the proposed models' on satellite-based data is comparatively lower
294 than the in-situ-based validation data, the observed difference in various validation metrics is rather insignificant. It

295 substantiates the efficiency of the proposed models in estimating OHC from satellite data at various depth extents over the
296 major oceanic basins. However, it should be noted that the validation results presented in this section are subject to vary with
297 the other sources of satellite-based SST and SSS data.

308

309 **4.3. Comparison with the contemporary satellite-based OHC models**

310 Comparison of our ANN models with the existing models is crucial to determine the relative uncertainty in the OHC estimates.
 311 Previously, an ANN algorithm suite was developed by the National Remote Sensing Centre (NRSC) of ISRO to disseminate
 312 the daily OHC products over the North Indian Ocean (40°E-120°E, 0°-30°N) at a spatial resolution of 0.25 degree (Ali et al.,
 313 2012; Jagadeesh et al., 2015). This algorithm suite includes ANN models to estimate OHC at multiple depth extents such as
 314 50 m, 100 m, 150 m, 200 m, 300 m, 500 m, and 700 m for the given input data of sea level anomaly (SLA), SST, and OHC_{clim,d}.
 315 It estimates OHC changes by utilizing the satellite altimetry-based SLA data from AVISO (Archiving, Validation, and
 316 Interpretation of Satellite Oceanographic data) data portal, SST from the Advanced Microwave Scanning Radiometer-2
 317 (AMSR2) onboard JAXA's Global Change Observation Mission 1st-Water (GCOM-W1), and climatological OHC from the
 318 World Ocean Atlas-2009 monthly climatological CTD profiles. The multilayer perceptron regressor algorithm of neural
 319 networks with three hidden layers was used to estimate OHC of all seven depth extents. The number of data points used to
 320 develop and validate the NRSC-ANN algorithm were 11472 and 2479, respectively. To estimate OHC changes at different
 321 depths, this algorithm employs the Celsius scale, in-situ temperature, and average density data instead of the Kelvin scale,
 322 conservative temperature, and instantaneous density, respectively (see Eq. 3 in Jagadeesh et al., 2015).

323 For this inter-comparison purpose, validation datasets were prepared for the period of 2017-2020 by calculating in-
 324 situ OHC in both Kelvin and Celsius scales for the depth extents of 50 m, 100 m, 150 m, 200 m, 300 m, 500 m, and 700 m.
 325 Daily OHC data were obtained from the NRSC's Bhuvan portal and collocated with the corresponding Celsius-scaled in-situ
 326 OHC data to evaluate the NRSC-ANN model products. Similarly, satellite-based SST and SSS data, and climatological TSL
 327 and OHC data were extracted by collocating with Kelvin-scaled in-situ OHC data for our ANN model to generate the OHC
 328 products. Evaluation of these two OHC products was done separately by means of the normalized metrics such as R, MBPE,
 329 and MAPE (Table 4).

330 **Table 4.** Statistical results for our ANN model and NRSC-ANN model obtained from another independent dataset of different
 331 depth extents used in this study.

Depth (m)	N	R		MBPE (%)		MAPE (%)	
		NRSC-ANN model	Proposed ANN model	NRSC-ANN model	Proposed ANN model	NRSC-ANN model	Proposed ANN model

332

333

334 As expected, our ANN model gave more accurate OHC estimates for all depth extents and hence yielded higher
335 correlation coefficients and lower errors as compared to the NRSC-ANN model. The accuracy of OHC estimates produced by
336 our ANN model also increased with depth in contrast to that of NRSC-ANN OHC estimates. Our ANN model was
337 accomplished with the selection of key input parameters based on a precise theoretical basis, accurate computation of in-situ
338 parameters, and selection of separate ANN architectures.

339 It should be mentioned that SLA is the combined outcome of temperature (thermosteric), salinity (halosteric), and
340 water mass changes in the oceanic water column. The direct use of satellite altimeter-derived SLA without eliminating
341 halosteric and water mass change components results in weaker correlations with OHC of various depth extents. Moreover,
342 the different time spans were used in the computation of the mean sea level at AVISO (1993-2012) and monthly climatology
343 data at WOA09 (1955-2006). The pair of merged SLA data from AVISO/CMEMS and climatological OHC data from WOA
344 could lead to discrepancies in OHC estimates. Under these considerations, the present study was focused on TSL modelling
345 rather than the Alt-GRACE approach (Meyssignac et al., 2019) to implement the ocean thermal expansion method to estimate
346 OHC changes.

347 Celsius scale can be used to compute in-situ OHC where the temperature gradient is always on the positive side. The
348 usage of the Celsius scale when the temperatures are less than zero and greater than the seawater freezing point is not
349 appropriate because of the potential negative values. In addition, the conservative temperature is an accurate variable compared
350 to the direct in-situ temperature or potential temperature. It represents the actual heat content of a mixture of two water masses
351 which are characterized by variations of salinity, pressure, and temperature (Pawlowicz, 2013). Thus, the conservative
352 temperature is defined in absolute scale (Kelvin scale) and used to calculate the in-situ OHC. On the other hand, employing
353 instantaneous density rather than average density is essential to account for the variations in seawater density which is
354 determined by temperature and salinity changes.

355 The vertical distribution of conservative temperature varies from equatorial to polar regions, and it follows a non-
356 linear profile with a mixed layer at the top, a thermocline at the middle, and a deep ocean layer at the bottom. This suggests
357 that it is appropriate to customize the ANN hyperparameters for each modelling depth. In this study, hyperparameter tuning
358 was performed for each modelling depth and it resulted in a better understanding of OHC patterns at various depth extents.
359 Though a clear improvement was achieved with the proposed OHC models, a relatively lower correlation was observed for
360 our ANN models in the depth range of 100-300 m over the North Indian Ocean (refer to Table 4). Similar results were obtained
361 for the NRSC-ANN models as well. It implies that the proposed ANN models less generalized the OHC patterns at the
362 intermediate depths over the North Indian Ocean. The underlying factors for the less generalized OHC patterns are described
363 in the following section. Nevertheless, the results demonstrated that the proposed ANN models contributed to improving the
364 accuracy and quality of OHC products through the ocean thermal expansion method.

365 **4.4. Potential sources of uncertainty in OHC estimates**

366 The relationship between the surficial parameters (SST and SSS) and depth-integrated parameters (TSL and OHC) is the prime
367 factor for determining the efficiency of the proposed OHC models of various depth extents (Klemas and Yan, 2014). This
368 relationship is mainly influenced by a wide range of geophysical processes including ocean currents, vertical mixing
369 (upwelling/downwelling), stratification, fronts, gyres, eddies, and air-sea interface processes. In addition, different climate
370 modes and oscillations, solar radiation, sea ice, phytoplankton growth, freshwater inputs, and winds can also be considered in
371 this context. Monthly climatological CTD profiles obtained from the WOA-18 database were objectively analyzed to calculate
372 the mean SST and SSS fields over a period of 1955-2017. Hence, these climatological data along with real-time SST and SSS
373 data enabled the ANN models to better generalize the prevailing geophysical processes and subsequent patterns in TSL &
374 OHC of various depth extents. The same can be perceived from the improved accuracy levels observed during the independent
375 validations carried out on unseen data (refer to Sects. 4.1 and 4.2) and the comparison with NRSC-OHC model products (Sect.
376 4.3).

377 It should be noted that the established relationship between the input parameters (surficial and climatological) and
378 output parameters (TSL & OHC patterns) may not hold great in the events of the above complex geophysical processes where
379 the physical oceanographic conditions differ significantly from the prevailing conditions. Moreover, the relative contributions
380 of these geophysical processes are subject to vary depending on the time and location of the water parcel in oceans. Slightly
381 lower accuracy of the proposed ANN models can be attributed to the influence of these complex geophysical processes. The
382 in-situ and satellite-based retrieval of all these atmospheric/surface/subsurface processes and their incorporation into the ANN
383 models is difficult because of the scarcity/sparsity of the required datasets in different spatial, temporal, and vertical scales.
384 The above factors constitute a potential source of uncertainty in OHC estimates and reduce the generalization ability of the
385 model. Further efforts are needed to better understand, quantify, and eliminate the different sources of observed uncertainties
386 caused by the complex geophysical oceanic processes. More number of in-situ CTD profiles are required to be collected and
387 analyzed in such oceanic regions to address the associated complex patterns and processes. Future releases of WOA will
388 certainly resolve the complex patterns in OHC data with the inclusion of newly collected CTD profiles over various oceanic
389 basins.

390 **5. A preliminary analysis of global OHC data**

391 This section presents a map of the global distribution of model-derived OHC estimates and its variation from 1993 to 2020.
392 This time period (1993-2020) was chosen based on the availability of satellite-based input data. The NOAA's AVHRR OISST
393 version 2.1 products are available from 1981 to present, but the ECMWF's ORAS5 SSS data are available from 1993 to 2020
394 only. Thus, for this preliminary analysis, daily OHC estimates were generated for the period from 1993 to 2020 and the
395 corresponding annual mean estimates were computed as shown in Figs. 8a and 8b. Subsequently, the OHC anomalies (OHCA)
396 were estimated by subtracting the annual mean data of 2020 from those of 1993 (Fig. 8c). It is worth mentioning that the heat

397 content estimates presented in this section cover all the modelling depths. The bathymetry values of each pixel were rounded
398 off to the nearest and lowest modelling depth (d) with the help of GEBCO-2020 bathymetry data (GEBCO Compilation Group,
399 2020), and the corresponding OHC_d values were considered for that pixel. As the proposed models are built for open oceanic
400 regions, the regions covered by sea ice are masked in both north and south poles by verifying the corresponding daily sea ice
401 concentration data obtained from the National Snow and Ice Data Center (Meier et al., 2021).

402 The spatial patterns of annual OHC product are nearly identical in both 1993 and 2020 (Figs. 8a and 8b). The relatively
403 higher OHC values (830 GJ m^{-2} - 840 GJ m^{-2}) at a depth of 700 m are observed over the North Atlantic subtropical gyre, Gulf
404 stream, north Arabian sea, eastern Mediterranean sea, and southeastern side of the Madagascar. Next, the OHC values of range
405 820 GJ m^{-2} - 830 GJ m^{-2} are observed over a vast portion of the major oceanic basins, namely the western parts of the north
406 Pacific ocean ($105^\circ \text{ E} - 150^\circ \text{ W}$, $0^\circ - 35^\circ \text{ N}$), the western and central parts of the south Pacific ocean ($115^\circ \text{ E} - 100^\circ \text{ W}$, $0^\circ -$
407 40° S), the north Atlantic ocean ($90^\circ \text{ W} - 30^\circ \text{ E}$, $0^\circ - 40^\circ \text{ N}$, excluding the north Atlantic subtropical gyre, the Gulf stream,
408 and the eastern Mediterranean sea), the southwestern half of the south Atlantic ocean ($55^\circ \text{ W} - 15^\circ \text{ E}$, $15^\circ \text{ S} - 40^\circ \text{ S}$), and the
409 Indian ocean ($25^\circ \text{ E} - 150^\circ \text{ E}$, $25^\circ \text{ N} - 40^\circ \text{ S}$, excluding the north Arabian sea and the southeastern side of the Madagascar).
410 Subsequently, the OHC values in the range of 810 GJ m^{-2} - 820 GJ m^{-2} are observed over the eastern part of the Pacific ocean
411 and equatorial Pacific ocean ($170^\circ \text{ E} - 70^\circ \text{ W}$, $45^\circ \text{ S} - 40^\circ \text{ N}$), northeastern part of the north Atlantic ocean ($50^\circ \text{ W} - 5^\circ \text{ W}$,
412 $40^\circ - 55^\circ \text{ N}$), the equatorial Atlantic ocean, the northeastern half of the south Atlantic ocean ($60^\circ \text{ W} - 25^\circ \text{ E}$, $0^\circ \text{ S} - 45^\circ \text{ S}$),
413 and the southeastern parts of the Indian ocean ($60^\circ \text{ E} - 150^\circ \text{ E}$, $30^\circ \text{ S} - 50^\circ \text{ S}$). And, the OHC values in the range of 780 GJ
414 m^{-2} - 810 GJ m^{-2} are observed in the latitudinal range of $40^\circ - 70^\circ$ in both the hemispheres with a decreasing trend from 40°
415 to 70° N . In the case of oceanic regions shallower than 700 m, the OHC values are observed to vary widely as shown in Figs.
416 8a and 8b.

417 Though the spatial patterns and magnitudes of OHC are almost same during the years 1993 and 2020, well-marked
418 warming/cooling regions can be observed in the order of $O(10^0)$ during 2020 with reference to 1993 (Fig. 8c). The ocean
419 warming of 1.5 GJ m^{-2} - 5 GJ m^{-2} is observed over the Red Sea, Kuroshio extension, Gulf Stream, and southern side of the
420 Africa ($30^\circ \text{ S} - 45^\circ \text{ S}$). On the other hand, cooling of the same range is observed over the north Atlantic subpolar gyre and
421 southern parts of the Indian Ocean. In addition, several eddy regions are also seen with warming/cooling patterns (Fig. 8c).

422 In a broader perspective, the observed spatial patterns in OHC and its temporal variation can be attributed to
423 consistent/anomalous warming/cooling in response to the ocean / atmospheric circulations, anthropogenic climate change and
424 internal variability. Consequently, a comprehensive analysis is to be carried out to gain new insights into the underlying
425 phenomena responsible for the observed OHC distributions and its variation in a separate study.

426
427

432 6. Conclusion

433 Accurate reconstruction of OHC and analysis of its regional patterns and long-term global records are critical for estimating
434 the Earth Energy Imbalance and understanding the evolution of the climate change. Owing to the lack of instrumentation to
435 cover geographic and depth ranges, OHC estimates from the in-situ measured temperatures are temporally limited and
436 insufficiently widespread to capture its spatiotemporal changes and structures. OHC estimates from either different mapping
437 methods or Ocean reanalyses (ORAs) have yielded large uncertainties in past studies. Thus, improving OHC estimates through
438 a novel satellite-based method is the major step forward to overcome sparse observations and reduce the uncertainty in OHC
439 trends. In this study, we proposed an artificial network model to estimate OHC changes in global oceans. The proposed ANN
440 model incorporates the ocean thermal expansion method as a promising tool to estimate OHC changes from satellite data.
441 Accurate implementation of the ocean thermal expansion method was challenging due to the inability of the present-day
442 satellite systems to directly measure the ocean thermal expansion/contraction component. In this study, we proposed a satellite-
443 based novel approach to better implement the ocean thermal expansion method by establishing a relationship between the
444 surficial parameters such as SST & SSS and subsurface T-S profiles. This model predicts the depth-integrated TSL component
445 by making use of SST & SSS data and then utilizes the predicted TSL to estimate OHC changes. For this application, we
446 developed ANN models for TSL and OHC of various depth extents such as 20 m, 30 m, 40 m, 50 m, 100 m, 150 m, 200 m,
447 250 m, 300 m, 350 m, 400 m, 450 m, 500 m, 550 m, 600 m, 650 m, and 700 m. The performance of these TSL & OHC models
448 was assessed by using in-situ-based independent data and satellite-based independent validation data, which were extracted
449 from the unseen in-situ CTD profiles of the Argo program. Observed high correlations and low errors indicated that the
450 proposed ANN models performed exceptionally good on unseen data of all depth extents without any overfitting and can be
451 used in conjunction with the sea ice thermodynamics-based OHC model of the ice-covered oceanic regions (Prakash and
452 Shanmugam, 2022) to better study the trends and patterns in three-dimensional distribution of OHC in the global oceans.

453 The model development and validation databases were prepared by using in-situ CTD profiles obtained from the Argo
454 program and collocated with the corresponding satellite-based daily data of SST (AVHRR v2.1) and SSS (ORAS5). The
455 multilayer perceptron regressor algorithm of deep neural networks was used and its architecture was optimized by evaluating
456 different combinations of hyperparameters for each modelling depth using the particle swarm optimization technique. Precise
457 consideration of theoretical aspects in the selection of input parameters, accurate computation of in-situ OHC, and customized
458 ANN architectures enabled the proposed models to establish the accurate relationships between the surficial parameters and
459 depth-integrated OHC (TSL) of various depths extents. The overall performance of the proposed models on satellite data was
460 good, suggesting that these models can be used for a variety of applications subjected to the accuracy requirements and can
461 produce accurate satellite-based OHC (TSL) estimates at various depth extents than previously possible. However, the
462 influence of complex geophysical processes on the generalization ability of ANN models is discussed, and realized that the
463 proposed models relatively less generalized the data in the events of complex geophysical processes. Further research should
464 focus on implementation of these models over the oceanic regions with complex geophysical processes. More number of in-

465 situ CTD profiles need to be collected and analyzed in such oceanic regions to address the associated complex patterns. Future
466 releases of WOA will certainly resolve the complex patterns in OHC data with the inclusion of newly collected CTD profiles
467 over various oceanic basins. However, the scope of the current research includes minimizing the observed marginal gap by
468 exploring new methods/parametrizations in satellite-based OHC modelling approaches.
